# Foreword

The Second Edition of “Sexually Transmitted Infections” represents a very substantial and useful contribution to the STI field, which today confronts many growing challenges. There has been continuing discovery of new sexually transmitted pathogens, in part through research and application of new technologies, and in part through emergence of new pathogens, such as HIV. A field that 50 years ago focused on five “venereal diseases” (gonorrhea, syphilis, chancroid, LGV, and granuloma inguinale), now encompasses over 30 different STI pathogens, with continuing emergence of many new variants or subspecies of these pathogens. We also recognize at least 30 different STI-related syndromes with most human organ systems affected by one or more STIs. There has been a disturbing resurgence of STIs in some populations over the past decade, coupled with declining susceptibility or outright resistance of major STI pathogens to important antimicrobial agents.

On the positive side, we do have many exciting new tools and approaches to provide evidence-based, cost-effective diagnosis, treatment and prevention for virtually all STIs. An objective of this textbook is to enable generalists and specialists from clinical, laboratory, and public health disciplines to understand and use modern tools and approaches appropriately. It is less and less acceptable today to sit back in a clinic to wait for the patient with an easily recognized or curable STI to appear at the door, undergo a few expensive tests, and return in a few days for single-dose curative treatment. There is a wide array of clinical presentations, etiologic possibilities, diagnostic and screening options, therapeutic challenges, multi-component prevention needs, health systems to be navigated, socio-behavioral risk factors;

and sex networks involving many diverse vulnerable populations require preventative interventions. All of this demands that health workers across many disciplines, STI program managers, and policy makers have accurate knowledge and understanding of STI, based upon up-to-date comprehensive sources of information.

Increasingly, answers to specific questions come from e-publications, easily accessed by computers and by smart phones. At the same time, there are great benefits to be gained from an integrated scientific overview that pulls together systematic advances together with authoritative but practical approaches.

With a growing number of highly distinguished authors representing many disciplines from throughout the world, this Second Edition of “Sexually Transmitted Infections” not only maintains its status as the best such STI textbook from India, with nearly a fifth of the world’s population, but ranks among the most authoritative STI textbook globally. I am honored to offer congratulations to the editors and authors Somesh Gupta and Bhushan Kumar and to the Section Editors for undertaking and executing what I know has been a huge but very rewarding task.

I am sure the book will be a great source of information and education to all who are involved with diagnosis, treatment, and/or prevention of sexually transmitted infections.

# Preface

Before the publication of the first edition of this book, no comprehensive reference text on the subject had ever been published from South Asia, particularly from India. Our goal in the first edition was to bring out a book with a definitive and fresh approach to the subject of Sexually Transmitted Infections (STIs). As the book was received well, we felt an imperative to provide a revised edition. We have been privileged to have received contributions from authors from many corners of the world, which makes this second edition truly international.

Our challenge in this edition was to distill the large amount of available knowledge on epidemiology, microbiology, physiology, molecular biology and therapeutics into a complete and scholarly presentation. To achieve such relevance, thoroughness, and practicality required a unique combination of scientific knowledge and clinical familiarity, best represented by the “academic physician”. Could the two of us have been able to do full justice to this? Obviously not. We, therefore, decided to divide the book into sections, and choose from the respective fields the experts to overlook these sections. They not only helped guide the style and content of the sections but also helped us find some of the best academicians and scientific physicians to contribute. Sharing this responsibility brought the best out of everyone and helped create a text that is truly encyclopedic, yet readable and accessible to all levels of readers.

Thus, the book has been reorganized, reformatted and substantially rewritten, with many new authors; it includes many new chapters, including those on social and legal issues, sexual abuse, and sexual dysfunction. The new edition covers clinical advances as well as issues that are becoming increasingly vital to STI specialists. We hope, it reflects the current state of science, practice, and the art of “Venereology”. Integration of basic and clinical sciences and therapeutics remain the highlight of the book. In a primarily clinical reference text, the space devoted to basic sciences must necessarily be restricted. However, a special effort has been made to ensure that these are reasonably easily understood by physicians whose interests and experience are primarily clinical. The effectiveness of any physician in practice ultimately depends on his ability to make an accurate diagnosis. Clinical descriptions have also been attempted to be as comprehensive as possible with many photographs, figures, and illustrations.

Many from the team who contributed to the first edition have also been included in the second edition. We would like to express our sincere gratitude for their efforts, which provided the framework upon which this edition has been expanded. We are also indebted to some of the previous edition contributors who generously allowed their material to be retained for the present edition, and also to those colleagues who donated color photographs.

It has been an exciting challenge to bring together such a wealth of expertise from countries all over the world, and to serve the entire community of Genitourinary/STI/Sexual Health physicians. We feel honored and are grateful to those experts, not only in WHO, CDC, and FHI, but also in many other institutions worldwide, who thought the project worthy of their support and contribution. The editorial team is grateful to Professor King Holmes for writing the Foreword for this edition.

We warmly thank the Authors and the Section Editors for their extraordinary dedication to a demanding time schedule that has allowed the timely publication of this edition. In addition to a thorough review by the Section Editors, many chapters have been read and critically analyzed and improved upon by other colleagues. We greatly appreciate and acknowledge the encouragement of all the friends, well-wishers, experts, critics, families and all.

We would also like to thank the Editorial team of Elsevier Health Sciences for their continued support, understanding and encouragement, and above all, their patience. In particular, Mr. Shravan Kumar, the Development Editor, Ms. Shabina Nasim (Managing Editor), and Ms. Richa Srivastava and Shrayosee Dutta (Copy Editors) all of whom helped to make the second edition so promptly available worldwide. We would also like to thank Ms. Deepti Talwar (Research Fellow) and Shashi Saldiwal (Medical Social Worker), who helped in the compilation of material.

We, the Editors and Section Editors, hope that the book will be of value to all those who are interested in the study of Sexually Transmitted Infections.

Happy reading!

University of North Carolina  
Medical Director for HIV/STD  
North Carolina DHHS, USA

**Peter Goon** PhD

Cancer Research UK,  
University of Cambridge,  
UK

**Philip Kell** MB BS MRCOG MFFP Dip GUM (LSA)

South Devon Healthcare Foundation Trust,  
Australia

**Phillip Hay** MBBS FRCP

Department of Infection, St. George's,  
University of London, UK

**Phillip J. Read** MBBS BSc DipGUM DFFP DipHIV MRCP MPH

Postgraduate Fellow, Sydney Sexual Health  
Center, & Conjoint Lecturer, School of Public  
Health and Community Medicine,  
University of New South Wales,  
Australia

**Pradeep Bambery** MD FRCP FRACP

Staff Specialist Physician  
Bundaberg Hospital  
Queensland, Australia

**Rachel Kachur** MPH

Behavioral Interventions and Research Branch,  
Division of STD Prevention, US Centers for  
Disease Control and Prevention, Atlanta,  
GA, USA

**Raj Patel** FRCP

Senior Lecturer/Consultant GU Medicine  
Southampton Sexual Health Services,  
Royal South Hants Hospital,  
Southampton, UK

**Rakesh Kochhar** MD DM

Professor, Department of Gastroenterology  
Postgraduate Institute of Medical Education  
and Research  
Chandigarh, India

**Rakesh Raman Patyar** PhD Fellow

Department of Cardiology  
Advanced Cardiac Center  
Postgraduate Institute of Medical Education  
and Research, Chandigarh, India

**Ramshekhar Menon** MD DNB DM

Assistant Professor, Department of  
Neurology  
Sree Chitra Tirunal Institute for Medical  
Sciences and Technology  
Kerala, India

**Ranjan Rawal** MD

Professor, Department of Skin and VD  
NHL Municipal Medical College  
Ahmedabad, India

**Ratnakar Kamath MD DNB FCPS DDV**

Assistant Professor  
Department of Dermatology,  
Venereology and Leprosy  
Grant Medical College and Sir JJ Group of  
Hospitals, Mumbai, India

**Ravi Chandra Sharma MD**

Former Professor & Head,  
Department of Skin & VD  
Lady Harding Medical College,  
New Delhi, India

**Ravinder Goswami DM**

Additional Professor,  
Deptt. of Endocrinology  
All India Institute of Medical Sciences  
New Delhi, India

**Rebecca Guy MD**

The Kirby Institute  
(formerly National Center in HIV  
Epidemiology and Clinical Research)  
University of New South Wales  
Sydney, Australia

**Rebecca Robey PhD**

Department of Medical Oncology  
Chelsea & Westminster Hospital  
London, UK

**Resham Vasani MD DNB FCPS DDV**

Assistant Professor  
Department of Dermatology,  
Venereology and Leprosy  
KJ Somaiya Hospital and  
Research Center, Sion, Mumbai, India

**Richard A. Crosby PhD DDI**

Endowed Professor and Chair  
Department of Health Behavior  
College of Public Health,  
University of Kentucky,  
Lexington, KY, USA

**Richard B. Pyles PhD**

Professor, Pediatrics; Microbiology and  
Immunology  
Director, IHII Molecular Epidemiology  
Laboratory  
Co-Director, GNL Assay Development  
Services Division  
Senior Scientist, SCVD  
University of Texas Medical Branch  
Galveston, TX, USA

**Richard Hillman FACHSHM**

Associate Professor  
Sexually Transmitted Infections Research  
Centre  
Faculty of Medicine, University of Sydney,  
Australia

**Robert De Rose PhD**

Department of Microbiology and  
Immunology  
University of Melbourne, Australia

**Roger G. Rank PhD**

Professor, Microbiology and Immunology  
University of Arkansas for Medical Sciences  
and Arkansas Children's Hospital Research  
Institute, Little Rock, AR, USA

**Roger J. Garsia MBBS (Hons) PhD Sydney**

University of Sydney (Central Clinical School),  
Sydney, Australia

**Rosanna W. Peeling PhD**

World Health Organization  
Geneva, Switzerland

**RS Paranjape PhD**

Director, National AIDS Research Institute  
Pune, India

**Rushi Deshpande MD DM DNB (Nephrology)**

Department of Nephrology  
Jaslok Hospital,  
Mumbai, India

**S. Joseph Wincelous FRCOG FRCP**

Consulting GUM/HIV Physician  
Genitourinary Medicine  
Kent and Sussex Hospital  
Kent, UK

**Sabine Kinloch-de Loes MD**

Department of Infection and Immunity  
University College London  
London, UK

**Saliya Hewagama FRACP**

Alice Springs Hospital  
Australia

**Samarjit Jana MD**

Principal, Sonagachi Research and  
Training Institute,  
Kolkata, India

**Sanchita Chakravarty PhD**

Biotech Consortium India Limited  
New Delhi, India

**Sandeep Grover MD**

Assistant Professor, Department of Psychiatry  
Postgraduate Institute of Medical Education &  
Research, Chandigarh, India

**Sangeetha Sundaram MRCP (UK)**

Specialty Registrar GU Medicine,  
Southampton Sexual Health Services, Royal  
South Hants Hospital, Southampton, UK

**Sara Head PhD**

Department of Communication,  
University of Kentucky, Lexington,  
KY, USA

**Sarla Malhotra MD**

Former Professor, Department of  
Obstetrics and Gynaecology  
Postgraduate Institute of Medical  
Education and Research  
Chandigarh, India  
Consultant Obstetrician and Gynecologist  
Fortis Multi Specialty Hospital  
Mohali, Punjab, India

**Saroj K. Sinha MD DM**

Additional Professor, Department of  
Gastroenterology  
Postgraduate Institute of Medical Education  
and Research  
Chandigarh, India

**Sathish Pai B. MD**

Professor, Department of Dermatology  
Kasturba Medical College, Manipal, India

**Satish K. Gupta PhD FNA FNASc FASc FNAMS**

Deputy Director, National Institute of  
Immunology  
Chief, Reproductive Cell Biology Laboratory  
National Institute of Immunology,  
New Delhi, India

**Savita Malhotra MD**

Professor, Department of Psychiatry  
Postgraduate Institute of Medical Education  
& Research  
Chandigarh, India

**Seth Noar PhD**

Associate Professor, Department of  
Communication,  
University of Kentucky, Lexington,  
KY, USA

**Shanthi Noriega Minichiello MPH**

FHI 360 Asia/Pacific Regional Office  
Bangkok, Thailand

**Shiva Prakash MD**

Deptt. of Endocrinology  
All India Institute of Medical Sciences  
New Delhi, India

**Shweta Malik MSc**

National Institute of Immunology  
New Delhi, India

**Sibongile Dlodlu MBChB MPH**

Johannesburg,  
South Africa

**Smriti Naswa MBBS**

Postgraduate Student  
Department of Skin & VD  
Medical College,  
Vadodara, India

**Somesh Gupta MD DNB MNAMS**

Associate Professor  
Department of Dermatology & Venereology  
All India Institute of Medical Sciences  
New Delhi, India

**Soni Nanda MD**

Consultant Dermatologist  
Max Hospitals  
New Delhi, India

**Srikanth Tripathy PhD**

National AIDS Research Institute  
Pune, India

**Stefan D. Baral MD MPH MBA**

Assistant Scientist, Johns Hopkins Bloomberg  
School of Public Health, Baltimore, MD,  
USA

**Stephen J. Kent MD**

Professor, Dept. of Microbiology and  
Immunology  
University of Melbourne,  
Australia

**Steven J. Reynold MD MPH**

Johns Hopkins School of Public Health  
Baltimore, USA

**Sudharshan S. MD**

Sankara Nethralaya, Medical and Vision  
Research Foundation  
Chennai, India

Associate Professor,  
Department of Dermatology, Venereology  
and Leprology  
Postgraduate Institute of Medical  
Education and Research,  
Chandigarh, India

**Sunil K. Arora PhD**

Additional Professor, Department of  
Immunopathology  
Postgraduate Institute of Medical Education  
and Research  
Chandigarh, India

**Sunil Sethi MD**

STD and TB Division, Department of  
Medical Microbiology  
Postgraduate Institute of Medical Education  
and Research, Chandigarh, India

**Suraj K. PhD**

Ottawa Hospital Research Institute  
Ottawa, Canada

**Surjit Singh MD DCH (London)**

Professor, Department of Pediatrics  
Postgraduate Institute of Medical Education  
and Research  
Chandigarh, India

**Suzanne M. Garland FRCPA FACHSHM MD  
FRANZCO Ad Eundem**

Director, Department of Microbiology and  
Infectious Diseases  
Professor, Department of Obstetrics and  
Gynaecology,  
University of Melbourne, The Royal Women's  
Hospital, Australia

**T. Puthanakit MD**

Division of Infectious Diseases  
Department of Pediatrics, Faculty of Medicine  
Chulalongkorn University, Bangkok, Thailand

**T.V. Gopalkrishnan MD**

Professor and Head,  
Harsha, Kochullur, Medical College Hospital  
Thiruvanthapura, India

**Tara McGinty MB BCH**

Mater Misericordiae University Hospital  
School of Medicine and Medical Sciences  
University College Dublin, Ireland

**Timothy Ryan MA**

Senior Public Health Consultant  
Bangkok, Thailand

**V. Usha DNB**

Consultant Dermatologist  
Thiruvanthapuram, India

**V.G. Padubidri MD**

Consultant Gynecologist and Obstetrician  
New Delhi, India

**Veerakathy Harindra FRCP, FRCP (Glasg)**

Department of Genitourinary Medicine  
St. Mary's Hospital,  
Portsmouth, UK

**Verapol Chandeying MD Dip Obgyn FAFPM  
FRCP FRCP**

Department of Obstetrics and Gynecology  
Faculty of Medicine, Prince of Songkla  
University  
Hat Yai, Thailand

**Vikram A. Londhey MD**

Associate Professor  
Medicine Department and Rheumatology  
Clinic  
TNMC and BYL Nair Ch Hospital,  
Mumbai, India

**Vineet Ahuja DM**

Additional Professor, Department of  
Gastroenterology  
All India Institute of Medical Sciences,  
New Delhi, India

**Walter H. Curioso MD MPH**

School of Public Health and Administration,  
Universidad Peruana Cayetano Heredia,  
Lima, Peru

**Yash Paul Sharma DM**

Additional Professor and Head  
Department of Cardiology  
Advanced Cardiac Center  
Postgraduate Institute of Medical Education  
and Research,  
Chandigarh, India

**Yogesh Chawla DM**

Professor & Head, Department of  
Hepatology,  
Postgraduate Institute of Medical Education  
and Research,  
Chandigarh, India

**Yogesh Marfatia MD**

Professor, Department of Skin and VD  
Medical College,  
Vadodara, India

# Contents

<i>Foreword</i> .....	<i>v</i>
<i>Preface</i> .....	<i>vii</i>
<i>Contributors</i> .....	<i>ix</i>

## section i Introduction

<b>Chapter 1</b> Sexual Health: Expanding Our Frame for Action .....	3
<i>Kevin A. Fenton</i>	
<b>Chapter 2</b> Historical Aspects of Sexually Transmitted Infections.....	10
<i>James S. Bingham</i>	

## section ii Epidemiology

— Christopher Fairley

<b>Chapter 3</b> Global Epidemiology of Sexually Transmitted Infections.....	27
<i>Ivonne Camaroni • Igor Toskin • Francis Ndowa • Antonio Carlos Gerbase</i>	
<b>Chapter 4</b> Global Epidemiology of HIV Infection .....	44
<i>Hammad Ali • Joanne Micallef • Basil Donovan</i>	
<b>Chapter 5</b> Sexual Behavior and Sexually Transmitted Infections.....	57
<i>Kaye Wellings</i>	
<b>Chapter 6</b> Surveillance for Sexually Transmitted Infections and HIV .....	64
<i>Rebecca Guy</i>	
<b>Chapter 7</b> Epidemiological Interactions between HIV-1 and other STI: A Complex, Continuing Narrative.....	74
<i>Brian P. Mulhall</i>	

## section iii Prevention and Control of Sexually Transmitted Infections and HIV

— Christopher Fairley

<b>Chapter 8</b> Prevention Strategies for the Control of Sexually Transmitted Infections .....	91
<i>Johannes van Dam</i>	
<b>Chapter 9</b> Behavioral and Counseling Aspects of Sexually Transmitted Infections (Including HIV) .....	99
<i>Michael W. Ross • Lena Nilsson Schönnesson</i>	
<b>Chapter 10</b> Role of Behavioral Interventions in Prevention and Control of Sexually Transmitted Infections and HIV.....	106
<i>Devinder Mohan Thappa • Amiya Kumar Nath</i>	
<b>Chapter 11</b> Condoms and Other Barrier Methods of STI and HIV Prevention .....	117
<i>Richard A. Crosby • Seth Noar • Sara Head • Elizabeth Webb</i>	

<b>Chapter 12</b>	Prevention of HIV and other Sexually Transmitted Infections: Male Circumcision.....	134
	<i>Natasha L. Larke • Helen A. Weiss</i>	
<b>Chapter 13</b>	Microbicides for Prevention of Sexually Transmitted Infections .....	139
	<i>G.P. Talwar • Kavita B. Garg</i>	
<b>Chapter 14</b>	Information and Communication Technologies to Support HIV and STI Care in Developing Countries .....	150
	<i>Walter H. Curioso • Magaly Blas • Antonio Bernabe-Ortiz • Freddy Canchihuaman • Patricia J. Garcia</i>	
<b>Chapter 15</b>	Vaccines for Sexually Transmissible Infections.....	161
	<i>Anna McNulty</i>	
<b>Chapter 16</b>	Vaccines for HIV .....	169
	<i>Stephen J. Kent • Amy Sexton • Ivan Stratov • Robert De Rose</i>	
<b>Chapter 17</b>	Partner Notification for Sexually Transmitted Diseases .....	177
	<i>Matthew Hogben • Rachel Kachur • Molly Dowling • Lauren Green</i>	

## section iv Public Health Aspects of STI Control

— Graham Neilsen

<b>Chapter 18</b>	Implementation of STI Programs.....	203
	<i>Gabriela Paz-Bailey • Jerry Owen Jacobson</i>	
<b>Chapter 19</b>	Integrating STI Prevention, Care, and Treatment with Other Sexual and Reproductive Health Services .....	220
	<i>Kathryn Church</i>	
<b>Chapter 20</b>	Monitoring and Evaluating Sexually Transmitted Infection Control Programs.....	234
	<i>Shanthi Noriega Minichiello • Timothy Ryan • Jerry Owen Jacobson • Gabriela Paz-Bailey</i>	

## section v Basic and Laboratory Sciences

— Jonathan Ross

<b>Chapter 21</b>	Anatomy of the Male Genital Tract .....	249
	<i>Ashini Jayasuriya • Madhur Gupta</i>	
<b>Chapter 22</b>	Anatomy of the Female Genital Tract.....	257
	<i>Ashini Jayasuriya • Madhur Gupta</i>	
<b>Chapter 23</b>	Normal Genital Flora .....	264
	<i>Frances E. Keane</i>	
<b>Chapter 24</b>	History and Physical Examination.....	269
	<i>Keith Radcliffe</i>	
<b>Chapter 25</b>	Genital Mucosal Immunity Against Sexually Transmitted Infections .....	275
	<i>Satish K. Gupta • Manoj Modi • Nutan • Nachiket Shembekar • Shweta Malik • Suraj K. • Sanchita Chakravarty</i>	
<b>Chapter 26</b>	Laboratory Diagnosis of Sexually Transmitted Infections .....	287
	<i>Krishna Ray</i>	
<b>Chapter 27</b>	Rapid Tests for the Detection of Sexually Transmitted Infections .....	321
	<i>Rosanna W. Peeling</i>	

## section vi Viral Sexually Transmitted Infections

— Raj Patel

<b>Chapter 28</b>	Genital Herpes Simplex Infections .....	335
	<i>Raj Patel • Sangeetha Sundaram • Bhushan Kumar</i>	
<b>Chapter 29</b>	Anogenital Human Papillomavirus Infection: Natural History, Epidemiology, and Vaccination.....	360
	<i>David Rowen • Paul Fox • Peter Goon</i>	

<b>Chapter 30</b>	Anogenital Warts, Intraepithelial Neoplasia, and their Clinical Management.....	366
	<i>Paul Fox • David Rowen</i>	
<b>Chapter 31</b>	Molluscum Contagiosum .....	374
	<i>Jyoti K. Dhar</i>	
<b>Chapter 32</b>	Hepatitis Viruses.....	380
	<i>Gary Brook • Yogesh Chawla</i>	
<b>Chapter 33</b>	Human Cytomegalovirus Infection .....	399
	<i>Krishna Ray • Manju Bala</i>	
<b>Chapter 34</b>	Epstein–Barr Virus Infections.....	412
	<i>Raj Patel</i>	
<b>Chapter 35</b>	Kaposi Sarcoma Herpesvirus .....	418
	<i>Rebecca Robey • Mark Bower</i>	

## section vii Bacterial Sexually Transmitted Infections

— Jonathan Ross

<b>Chapter 36</b>	Infectious Syphilis.....	429
	<i>Patrick French • Somesh Gupta • Bhushan Kumar</i>	
<b>Chapter 37</b>	Late Syphilis.....	458
	<i>Ashish Sukthankar • Anne M. Rompalo</i>	
<b>Chapter 38</b>	Endemic Treponematoses .....	467
	<i>C. Balachandran • Sathish Pai B</i>	
<b>Chapter 39</b>	Gonococcal Infections.....	473
	<i>Bellum Shiva Nagi Reddy • Sujay Khandpur • Sunil Sethi • Magnus Unemo</i>	
<b>Chapter 40</b>	Chlamydia Trachomatis Infections .....	494
	<i>Nicola Steedman</i>	
<b>Chapter 41</b>	Lymphogranuloma Venereum.....	506
	<i>Henry JC de Vries • Bellum Shiva Nagi Reddy • Sujay Khandpur</i>	
<b>Chapter 42</b>	Chancroid.....	522
	<i>Soni Nanda • B. Viswanath Reddy • Bellum Shiva Nagi Reddy</i>	
<b>Chapter 43</b>	Donovanosis.....	533
	<i>Nigel O'Farrell</i>	
<b>Chapter 44</b>	Bacterial Vaginosis.....	542
	<i>Phillip Hay • Verapol Chandeying</i>	
<b>Chapter 45</b>	Pelvic Inflammatory Disease .....	557
	<i>Jonathan D.C. Ross</i>	
<b>Chapter 46</b>	Genital Mycoplasmas.....	569
	<i>Jørgen Skov Jensen</i>	
<b>Chapter 47</b>	Sexually Transmitted Anorectal Infections and Enteric Bacterial Infections .....	578
	<i>Jason C.B. Goh • S. Joseph Wincelous</i>	

## section viii Fungi, Protozoa, and Arthropods

— Charlotte A. Gaydos

<b>Chapter 48</b>	Genital Candidal Infections.....	591
	<i>P. Janet Say</i>	

<b>Chapter 49</b>	Trichomonas Vaginalis Infections..... <i>Barbara Van Der Pol</i>	602
<b>Chapter 50</b>	Intestinal Protozoa ..... <i>Lara Stabinski • Mahesh Sharma • Vineet Ahuja</i>	610
<b>Chapter 51</b>	Scabies and Pediculosis Pubis..... <i>Peter Leone • T.V. Gopalkrishnan • V. Usha</i>	621

## section ix Sexually Transmitted Infection Syndromes and their Management

— Antonio Carlos Gerbase

<b>Chapter 52</b>	The Syndromic Approach for the Management of STIs: An Overview..... <i>Ahmed S. Latif</i>	633
<b>Chapter 53</b>	Genital Ulcer-Adenopathy Syndrome..... <i>Francis Ndowa • Fatim Cham • Sibongile Dlodlu</i>	643
<b>Chapter 54</b>	Urethral Discharge ..... <i>Francis Ndowa • Sibongile Dlodlu</i>	652
<b>Chapter 55</b>	Epididymitis and Epididymo-orchitis ..... <i>Francis Ndowa • Sibongile Dlodlu</i>	658
<b>Chapter 56</b>	Abnormal Vaginal Discharge: Syndromic Management..... <i>Verapol Chandeying • Nutthaporn Chandeying</i>	662
<b>Chapter 57</b>	Syndromic Management of Lower Abdominal Pain in Women ..... <i>Ahmed S. Latif</i>	679
<b>Chapter 58</b>	Inguinal and Femoral Buboes..... <i>Somesh Gupta • Bhushan Kumar</i>	683

## section x Genital Dermatology and Genital Pain Syndrome

— Mikhail Gomberg

<b>Chapter 59</b>	Balanitis and Balanoposthitis ..... <i>Michael Waugh • Sunil Dogra</i>	691
<b>Chapter 60</b>	Non-venereal Penile Dermatoses ..... <i>Christopher B. Bunker</i>	703
<b>Chapter 61</b>	Vulvar Dermatoses..... <i>Mohammed Sharaf • Jennifer Gloeckner Powers • Andrew T. Goldstein • Nellie Konnikov</i>	728
<b>Chapter 62</b>	Vulvar Vestibulitis Syndrome..... <i>Jorma Paavonen • Leila Unkila-Kallio • Päivi Tammola</i>	744
<b>Chapter 63</b>	Male Genital Pain Syndromes..... <i>G.A. Luzzi • D. Mandal</i>	747

## section xi Sexually Transmitted Syndromes and Other Organ Systems

— Jonathan Ross

<b>Chapter 64</b>	Ocular Manifestations of Sexually Transmitted Infections..... <i>Jyotirmay Biswas • Parthoprati Dutta Majumder • Sudharshan S.</i>	759
<b>Chapter 65</b>	Arthritis Associated with Sexually Transmitted Infections..... <i>Pradeep Bamberg</i>	768

## section xii HIV Infection and AIDS

### Part A HIV Infection: Biology, Laboratory Science, Clinical Pharmacology, and Therapeutics

— Brian P. Mulhall

<b>Chapter 66</b>	Human Immunodeficiency Virus: Biology and Natural History of Infection.....	779
	<i>Sunil K. Arora • R.S. Paranjape • Srikanth Tripathy • Ajay Wanchu</i>	
<b>Chapter 67</b>	HIV Diagnosis .....	795
	<i>Jessica Markby • Claire Ryan</i>	
<b>Chapter 68</b>	Pharmacology of Antiretroviral Drugs.....	805
	<i>Tara McGinty • Patrick W.G. Mallon</i>	
<b>Chapter 69</b>	Surrogate Markers of Antiretroviral Efficacy .....	826
	<i>Julian H. Elliott • Johan Van Griensven • James McMahon • Lutgarde Lynen</i>	
<b>Chapter 70</b>	First Decade of ARV in Africa: Overcoming Barriers to Providing ARV Therapy in Resource-Limited Settings..	831
	<i>Nathan Ford • Alexandra Calmy</i>	
<b>Chapter 71</b>	Antiretroviral Drugs for HIV Prevention .....	836
	<i>Hubert Maruszak • Don Smith • Brian P. Mulhall</i>	

### Part B Clinical Presentations

— Janak K. Maniar

<b>Chapter 72</b>	Acute HIV Infection .....	843
	<i>Sabine Kinloch • Steven J. Reynold • Robert C. Bollinger</i>	
<b>Chapter 73</b>	Opportunistic Infections .....	849
	<i>Hiten Thaker • A.V. Balaji</i>	
<b>Chapter 74</b>	Mucocutaneous Manifestations of HIV .....	871
	<i>Yogesh Marfatia • Ranjan Rawal • Keyur Shah • Smriti Naswa</i>	
<b>Chapter 75</b>	Pulmonary Manifestations of HIV Disease .....	894
	<i>Resham Vasani • Ratnakar Kamath • J.K. Maniar</i>	
<b>Chapter 76</b>	Neurological Manifestations of HIV .....	910
	<i>Arun B. Shah • Ramshekhhar Menon</i>	
<b>Chapter 77</b>	Gastrointestinal Manifestations of HIV Infection and AIDS.....	927
	<i>Saroj K. Sinha • Rakesh Kochhar</i>	
<b>Chapter 78</b>	Renal Manifestations of HIV Infection and AIDS .....	951
	<i>Frank Post • Rushi Deshpande</i>	
<b>Chapter 79</b>	HIV and Endocrine Manifestations .....	960
	<i>Shiva Prakash • Ravinder Goswami</i>	
<b>Chapter 80</b>	AIDS Associated Malignancies and Their Treatment .....	966
	<i>Mark Bower • David Shackleton • Justin Stebbing</i>	
<b>Chapter 81</b>	Rheumatic Manifestations of HIV and AIDS .....	980
	<i>Vikram A. Londbhey • Milind Y. Nadkar</i>	
<b>Chapter 82</b>	Cardiac Involvement in HIV Infection/AIDS .....	988
	<i>Yash Paul Sharma • Rakesh Raman Patyar</i>	
<b>Chapter 83</b>	Ocular Manifestations of HIV Infection and AIDS .....	993
	<i>Jyotirmay Biswas • Kaushal Bhavsar • Sudharshan S.</i>	
<b>Chapter 84</b>	Sexually Transmitted Infections in HIV-Infected Patients .....	1003
	<i>V. Harindra</i>	

**Part C Human Immunodeficiency Virus Infection in Special Groups**

— Brian P. Mulhall

<b>Chapter 85</b>	Human Immunodeficiency Virus Infection in Women.....	1016
	<i>Noreen A. Hynes • Jean Anderson • Adriana Andrade</i>	
<b>Chapter 86</b>	HIV in Children.....	1025
	<i>J. Lucey • C. Foster • T. Puthanakit • J. Ziegler • P. Palasanthiran</i>	
<b>Chapter 87</b>	HIV Infection in Homosexual Men .....	1037
	<i>Mark Bloch • Brian P. Mulhall • Charles Farthing • Richard Hillman</i>	
<b>Chapter 88</b>	HIV in Blood and Blood Product Recipients.....	1050
	<i>Roger J. Garsia</i>	
<b>Chapter 89</b>	HIV in Injection and Other Drug Users .....	1061
	<i>Jaimie P. Meyer • Frederick L. Altice</i>	

**section xiii Sexually Transmitted Infections in Special Groups of Populations**

— Mikhail Gomberg

<b>Chapter 90</b>	Sexually Transmitted Infections and Pregnancy .....	1081
	<i>Sarla Malhotra</i>	
<b>Chapter 91</b>	Sexually Transmitted Infections in Neonates and Infants.....	1095
	<i>P. Janet Say • Ravi Chandra Sharma</i>	
<b>Chapter 92</b>	Congenital Syphilis .....	1103
	<i>Carlos Velásquez • Cristina Guerra-Giraldez • Lorenzo Giacani • Arturo Centurion-Lara • Patricia J. García</i>	
<b>Chapter 93</b>	Sexually Transmitted Infections and Infertility.....	1121
	<i>V.G. Padubidri • Sarla Malhotra</i>	
<b>Chapter 94</b>	Aging, Sexual Behavior, and HIV/STI Risk .....	1129
	<i>Massimo Giuliani</i>	
<b>Chapter 95</b>	Sexually Transmitted Infections in the Female Sex Worker Community .....	1136
	<i>Samarjit Jana • Geeta Sethi • D. Mandal</i>	
<b>Chapter 96</b>	Sexually Transmitted Infections Associated with Sexual Assault .....	1146
	<i>P. Janet Say</i>	
<b>Chapter 97</b>	Sexual Health of Migrant Populations.....	1153
	<i>Andy J. Williams • Beng T. Goh</i>	

**section xiv Human Sexuality, Sexual Orientation, and Special Issues**

— Darren Russell

<b>Chapter 98</b>	Human Sexuality .....	1165
	<i>D. Narayana Reddy</i>	
<b>Chapter 99</b>	Homosexuality, Bisexuality, and Sexual Orientation .....	1174
	<i>David Bradford</i>	
<b>Chapter 100</b>	Sexually Transmitted Infections among Women who have Sex with Women .....	1179
	<i>Jeanne Marrazzo • Devika Singh</i>	
<b>Chapter 101</b>	Sexually Transmitted Infections in Transgender .....	1188
	<i>Darren Russell</i>	
<b>Chapter 102</b>	Sexual Abuse in Children.....	1192
	<i>Savita Malhotra • Nitin Gupta • Anindya Banerjee</i>	

<b>Chapter 103</b>	Male Sexual Dysfunction.....	1203
	<i>Phillip Kell</i>	
<b>Chapter 104</b>	Women's Sexual Dysfunction .....	1210
	<i>Verapol Chandeying</i>	
<b>Chapter 105</b>	Sexuality Education for Young People .....	1221
	<i>Anne Mitchell • Jenny Walsh</i>	
<b>Chapter 106</b>	Dhat Syndrome: A Culture-Bound Sex Related Disorder in Indian Subcontinent.....	1225
	<i>Ajit Avasthi • Sandeep Grover • Om Prakash Jhirwal</i>	

## section xv      **Miscellaneous**

— *Charlotte A. Gaydos*

<b>Chapter 107</b>	Clinical Services for Sexually Transmitted Infections and HIV.....	1231
	<i>Joyce Jones • Emily Erbeling</i>	
<b>Chapter 108</b>	Medicolegal Aspects of Sexually Transmitted Infections and Sexual Assault .....	1236
	<i>Margaret R. Hammerschlag</i>	
<b>Chapter 109</b>	Sexually Transmitted Infections: Screening and Diagnostic Practices .....	1242
	<i>Charlotte A. Gaydos</i>	
<b>Chapter 110</b>	Sexually Transmitted Infections Related Genital Neoplasias .....	1251
	<i>Suzanne M. Garland</i>	
<b>Chapter 111</b>	HIV, Sexually Transmitted Infections, and Human Rights .....	1259
	<i>Chris Beyrer • Stefan D. Baral</i>	
<b>Chapter 112</b>	Animal Models of Sexually Transmitted Infections.....	1269
	<i>Roger G. Rank • Richard B. Pyles</i>	

## section xvi      **Guidelines for the Management of Sexually Transmitted Diseases and HIV**

— *Basil Donovan*

<b>Chapter 113</b>	Guidelines for the Management of Sexually Transmitted Infections .....	1299
	<i>Ahmed S. Latif • Charles Mutandwa</i>	
<b>Chapter 114</b>	Guidelines for the Treatment of HIV in Industrialized and Middle Income Countries— Adults, Adolescents, and Pediatric .....	1310
	<i>Saliya Hewagama • Jennifer Hoy</i>	
<b>Chapter 115</b>	Guidelines for the Treatment of HIV and AIDS in Resource-Limited Countries .....	1328
	<i>Chris Duncombe • Deepti Suri</i>	
<b>Chapter 116</b>	Guidelines for Prevention of Perinatal HIV Infection.....	1345
	<i>Surjit Singh • Deepti Suri</i>	
<b>Chapter 117</b>	Guidelines for the Management of HIV-Associated Opportunistic Infections.....	1358
	<i>Phillip J. Read</i>	
	Index .....	1369

Kevin A. Fenton

## Introduction

Sexually transmitted infections (STIs) are among the most commonly diagnosed and notifiable infectious diseases in many parts of the world, with more than 450 million new cases of curable STIs occurring in adults each year.<sup>1,2</sup> In 2005, the total number of new cases of the four curable STIs was estimated to be 448 million—101.5 million cases of chlamydia, 87.7 million cases of gonorrhea, 10.6 million cases of syphilis, and 248.5 million cases of trichomoniasis.<sup>3</sup> STIs constitute a huge health and economic burden, especially for developing countries, where they account for 17% of the economic losses caused by ill health.<sup>4</sup> The associated costs include direct costs, both medical and nonmedical, for care and materials, and indirect costs of time spent sick, when individuals are unable to engage in productive activities.<sup>5</sup> In the United States, STIs account for an estimated \$15.9 billion annually to the healthcare system.<sup>6</sup> However, treatment costs for STIs vary tremendously between countries and are influenced by a range of factors, including delivery by the public or private sector; economies of scale; economies of scope; prevalence and incidence; epidemic phase; transmission efficiency; resource combinations and input prices; incentives to providers for high quality and quantity of service delivery; and willingness to pay for treatment as a function of price, income, and distance.

STIs consistently rank among the top 10 reasons for healthcare visits in most developing countries and substantially drain national health budgets and household income. Care for the complications of untreated STIs accounts for a large proportion of tertiary healthcare costs in terms of screening and treatment of cervical cancer, management of liver disease, investigation of infertility, care for perinatal morbidity, childhood blindness, and chronic pelvic pain. Stigma and discrimination constitute an additional burden on people living with and affected by STI/HIV, and their effect is partly mediated through economic mechanisms (e.g.,

limitations on education, employment, and housing), which affect the household's ability to generate income or to use its income to secure improved quality of life. Clearly, STIs, including HIV infection, remain major global public health concerns.

Historical approaches to the prevention and control of these infectious diseases have largely centered around the principles of prompt diagnosis and treatment of infected individuals and their infected or exposed partners; community and risk-group education and awareness; effective program leadership and governance; and program integration and health systems strengthening.<sup>7</sup> However, despite the availability of effective clinical, behavioral, and community-level interventions,<sup>8</sup> we continue to wage a losing battle against STIs in many settings, and in some populations, previously controlled STI epidemics are now resurgent.<sup>9</sup> These challenges have led to calls for a strategic refocusing of global HIV/STI prevention priorities and efforts, accompanied by increases in program-relevant research that aim to bring to scale the most effective interventions; combine effective approaches for greater effect; and address both the individual and contextual determinants of these adverse health outcomes.<sup>10</sup>

It is within this context that recent discussions at national, regional, and global levels have focused on the benefits of incorporating the more holistic approach of sexual health to complement and enhance current prevention efforts. Sexual health has been defined by the World Health Organization as “*a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence*.”<sup>11</sup> Sexual health has considerable potential as a framework to guide and support national efforts to control STIs, to reduce associated adverse health outcomes, and to promote prevention and wellness. This introductory chapter introduces the concept of sexual health as a broader, more holistic

framework for understanding both the multi-level determinants of STI epidemics, and for refocusing on prevention and control efforts. The chapter also explores some of the challenges and potential benefits of adopting this strategic framework, and highlights potential steps for future action.

## Determinants of Sexual Health

Sexuality is a fundamental aspect of human life, carrying the potential to create new life and fulfilling both personal and social needs.<sup>12</sup> However, many adverse health outcomes result from unhealthy or otherwise uninformed sexual behaviors and attitudes, including HIV and other sexually transmitted infections, unintended pregnancies, and coercive behavior. If health is more than the mere absence of disease, then current conceptual frameworks for describing the distribution and determinants of disease within a population (a dynamic interaction among the host, environment and treatment and care services) should be expanded since the fundamental determinants of health at the population level are patterns of exposure and the social and economic, as well as physical, environments.<sup>13–15</sup> Similarly, adopting a sexual health approach requires a more inclusive frame in which not only the characteristics of the infectious agent; the nature, form, and effectiveness of prevention, treatment, and care services; individual characteristics; patterns of sexual behavior; and the characteristics of sexual networks; but also the more distal social and cultural environment, including norms and values, are incorporated into our understanding of determinants and help to shape our intervention responses. To optimize the benefits of sexual health throughout the lifespan and to reduce the adverse consequences stemming from unhealthy sexual behaviors, intervention opportunities to improve sexual health should be considered at every level of society from individuals and sexual partnerships to communities and public infrastructure (including government).<sup>16</sup>

## Infectious Agents

A wide variety of microorganisms (bacteria, viruses, fungi, and protozoa) and a few ectoparasitic arthropods (*Pediculus pubis*, *Sarcoptes scabiei*) have evolved to depend, in whole or in part, upon the human genital tract and human sexual behavior for their survival.<sup>17</sup> Including HIV-1, more than 30 pathogenic sexually transmissible agents identified to date are responsible globally for an enormous degree of aggregate morbidity and mortality. The dynamic interaction between these agents, individual sexual behavior and networks, and health systems drives the observed patterns and distribution of disease in the population. Because sexual behavior is essential to preservation of the species and is driven by a highly developed neurochemical pleasure reward system, it offers both a reliable ecological niche for infectious agents and a daunting challenge to modern-day practitioners of medicine and public health who endeavor to treat and control them.<sup>17</sup>

The continued spread and evolution of these infectious agents greatly influence the patterns of disease transmission and, ultimately, sexual health. Of major concern is the emergence of

antimicrobial resistance of some of these agents and the growing number of restrictions on the range of available antimicrobial agents for treating these conditions.<sup>18,19</sup> Other changes may make the infectious agents more virulent or may change their clinical manifestations.<sup>17</sup> Finally, their impact is determined not only by their effect on the immediate genital environment, but also by their more widespread effects and complications, further driving up costs, and causing additional morbidity and mortality.<sup>20</sup>

## Individual Factors

Individual characteristics, including patterns of individual sexual risk behavior, remain major determinants of the risk of acquiring an STI and therefore of sexual health.<sup>21,22</sup> There are several biological factors that make it easier or more difficult for STI (including HIV) acquisition, including the presence of other STIs, tissue or membrane vulnerability, and viral load.<sup>23–25</sup> In addition, an individual's pattern of sexual behavior, including the number of partners, and the spacing and rate of partner change, and the types and frequency of sexual practices, greatly influence STI transmission risk.<sup>21</sup> Given the highly social nature of sexual partnerships, individual behavior takes place within the context of sexual partnerships and often of sexual networks (a set of people who are linked directly or indirectly through sexual contact).<sup>26,27</sup> The pattern of linkages can drastically influence such health outcomes in a population as the transmission of HIV and other STIs.<sup>28</sup> With regard to disease transmission, the important characteristics of a network are its size and its density or connectivity.<sup>29</sup> Because networks are dynamic, with new linkages forming and old ones dissolving, time and place are important dimensions of networks which may evolve rapidly, especially in an era in which the internet, travel, and migration all play important roles in disease transmission and in the creation and dissemination of sexual norms and social values.<sup>30–32</sup>

Other individual characteristics such as, educational attainment, occupation, income level, sex and race or ethnicity, and sexual orientation can influence a person's position in the social hierarchy and consequently can influence one's risk of acquiring HIV and STIs.<sup>33–35</sup> When we take a broader view of sexual health, we see that these individual-level factors may directly affect the probability both of one's being exposed to the infectious agent and to one's increased vulnerability of exposure to transmission networks. They also represent an opportunity for intervention. Traditional approaches to STI prevention have focused primarily on getting individuals screened, tested, and treated for STIs, but it is increasingly recognized that approaches must be tailored both to meet the specific characteristics of the individual and to ensure the acceptability and cultural competency of the intervention. From a practical standpoint, it is essential that STI care providers be familiar with locally prevalent sexual practices and that they be able to assess individual risk of infection for STI and for transmission to partners. It is important to know which sexual behaviors can transmit which specific agents and to avoid making assumptions about who is practicing what types of behaviors.

## PREVENTION, TREATMENT, AND CARE SERVICES

The earlier STIs can be diagnosed, the earlier they can be treated and further transmission interrupted. Therefore ready access to, and uptake of high-quality and effective care are essential components of effective STI control strategies. This requires at-risk or infected persons to have access to stable, simple, rapid, inexpensive, and accurate diagnostic tests; high-quality clinical services that allow easy, affordable, and stigma-free treatment; effective behavioral and biomedical interventions to arrest disease spread and reduce high-risk behaviors; trained, culturally competent healthcare workers to provide consistent service; and data and information systems that allow monitoring of progress, impact evaluation, and quality improvement.<sup>36</sup>

There continues to be major progress with new diagnostic tests for STIs, including newer-generation nucleic acid amplification tests and an expansion of novel point-of-care diagnostics.<sup>37,38</sup> New preventive vaccines provide mixed hope for viral STI control. An effective, inexpensive, safe vaccine against hepatitis B has been available worldwide for almost 40 years, yet elimination remains a question of time, public will, and priorities.<sup>39</sup> The availability of new human papillomavirus (HPV) preventive vaccine is encouraging, although the expense and limited availability globally will severely restrict its potential to make great inroads on disease incidence in resource-poor settings.<sup>40,41</sup> For herpes simplex virus 2 (HSV-2), except for partial protection of seronegative women provided by one vaccine candidate, controlled trials of several others have failed.<sup>42</sup> Efforts to develop vaccines to prevent HIV have been complicated, costly, and disappointing, and although work on HIV vaccine continues, it will likely be 5–10 years or more before an effective vaccine is marketed.<sup>43</sup> While there is not yet a cure for HIV infection, there are a growing number of treatments that can extend life expectancy for those who have access to them.<sup>44</sup>

Access to high-quality curative services remains a challenge around the world, and too many people with acute STIs, or living with HIV, do not have access to the medical care that they need. Furthermore, the recent global economic crisis has caused a number of countries to scale back or reduce funding for STI programs, further complicating access and impact. Waiting lists to gain access to clinical services and other limitations on life saving HIV medications are increasing concerns in developing and developed country settings.<sup>45–47</sup> Having an adequate and accessible health workforce is fundamental to an integrated health system and for providing essential health services in developing countries.<sup>48</sup> The severe shortage of healthcare workers in many developing countries constitutes a major threat to the performance of health systems and undermines the ability of these countries to achieve the Millennium Development Goals and other internationally agreed upon development priorities.<sup>49</sup> The situation is exacerbated by the emigration of highly educated and trained healthcare personnel from countries with health systems in crisis, further weakening the health systems in their countries of origin.<sup>50</sup>

Efforts to promote sexual health must therefore incorporate and engage the health system as a major determinant of health outcomes. In addition to the traditional approaches of diagnosing, treating, and reporting infections, the health system provides an opportunity for improving linkages through program collaboration, for strengthening holistic service provision through appropriate client-level service integration, and for facilitating seamless referrals to supportive services that address the wider determinants. Training of healthcare providers to manage STIs competently is critical, but so too is building the workforce capacity to understand, recognize, and manage the broader determinants of sexual ill health.

## SOCIAL CONTEXTS

The term “social context” refers to demographic, socioeconomic, macroeconomic, sociopolitical, and related features of the individual’s environment. Economic forces, demographic features, and other structural aspects of society outside the individual’s control play an important role in epidemiological factors and individual behaviors, including sexual behaviors, transmission of STIs, and other health outcomes.<sup>51,52</sup> Community attributes—including poverty, rates of substance abuse, sex roles, norms for sexual behavior, and prevalence of STIs—can increase the frequency of and risk associated with individual behaviors and can impede the ability of individuals to adopt preventive behaviors. These social determinants, which are complex and, integrated with overlapping social structures and economic systems, are linked to a lack of opportunity and to a lack of resources to protect, improve, and maintain health. Structural and societal factors such as social and physical environments, and availability, cost of, and access to health services, create pathways or barriers to good health. These factors are affected by the distribution of money, power, and other resources, all of which can be addressed through policy. Environmental factors, such as housing conditions, social networks, and social support also are key drivers for infection with HIV and other STIs.<sup>34</sup> Many have argued that a sustained and effective response to STIs and their adverse outcomes will be achieved only when we move beyond controlling disease on the individual level and address the root causes of disease, including the social and environmental determinants of health.<sup>53–56</sup> Adopting a sexual health framework provides an opportunity to look beyond simply managing disease outcomes to incorporating a more holistic approach to achieving health.

## Sexual Health: Challenges and Opportunities

Numerous countries now have experience with adopting or integrating a sexual health approach to enhance their HIV/STI prevention efforts.<sup>57–59</sup> While rigorous evaluations of this strategy remain to be undertaken, the literature suggests that there are likely to be both varied understandings of the utility of this approach, as well as challenges and benefits to implementation.<sup>60</sup> The highly stigmatized nature of STIs (including HIV infection), sexual behavior, and human sexuality in many societies often

complicates efforts to speak openly about these issues, or to broaden the conversation to include sexual health. In other settings, sexual health-related issues, including HIV stigma and criminalization, discrimination on the basis of sexual orientation, sexual violence, and reproductive health have come to be focal points for political, religious, or social debate. Misunderstanding or misinterpreting what is included in, or intended by, sexual health, and how it can be achieved, may also make providers, policy makers, and communities reluctant to adopt this approach. Questions about the role of the public sector in what is perceived by many as an intensely private matter further complicate the issue. While none of these challenges is insurmountable, the ability to promote sexual health effectively at local, state, national, and global levels requires a realistic assessment of the opportunities for change; identification of the challenges facing implementation; engagement and mobilization of a wide cross-section of partners; and a commitment to utilize long-term strategic approaches to achieve change.

Nevertheless, there are potential benefits and opportunities for adopting or integrating sexual health into current HIV/STI prevention efforts. Sexual health provides a holistic approach to addressing STIs and related conditions that may be more legitimately added to, or integrated into broader governmental initiatives aimed at promoting health and wellness.<sup>57–59</sup> Placing sexual health alongside mental or cardiovascular health may legitimize conversations on STIs, HIV and reproductive health in otherwise challenging contexts. Sexual health has already been included in national strategic approaches to address HIV/AIDS,<sup>57–59</sup> allowing for a broader discussion and integration of other STIs, sexual behaviors, and reproductive health issues and for addressing stigma related to these issues.

Incorporating a sexual health frame to complement existing vertical programs may allow those involved in HIV/STI control to move beyond the siloed nature of their efforts, and to engage a wider range of strategic partners in their efforts, including those in reproductive, adolescent, school health and mental health.<sup>61,62</sup> This may be especially useful for engaging constituencies who may consider disease-specific targeted approaches more sensitive or stigmatizing. For example, great strides are being made in engaging faith communities around HIV/AIDS and sexual health, and many of these communities recognize the intrinsic value of sexual health and the glaring and urgent health inequities.<sup>63,64</sup> Similarly, for social or economically marginalized groups, including migrants; for lesbian, gay, bisexual, and transgender (LGBT) communities; and for drug users, a focus on sexual health may provide a more empowering way to engage in and to support positive action for change by focusing on the social context that places them at risk, not solely on the individual risk behaviors and adverse health outcomes.<sup>65,66</sup>

Adopting a sexual health frame may also facilitate improved integration and synergy through promoting combined messages and services.<sup>67</sup> Collaboration across prevention programs and appropriate service integration at the client level has been identified as a key structural intervention to enhance HIV/STI prevention

and control efforts.<sup>68,69</sup> Similarly, there has been increasing interest to deliver and evaluate the quality and benefits of integrating health messages between and across health concerns, as well as evaluating the combined benefits of effective actions.<sup>70–72</sup> This integrated approach to messaging and to providing services may be facilitated through adopting the broader sexual health frame, and it remains an area for evaluation and research.

## Sexual Health: From Theory to Action

Incorporating and implementing sexual health as part of our targeted efforts to prevent, treat, and control STIs provides an opportunity to take a broader approach to prevention, one that acknowledges and incorporates external contexts and the wider determinants of adverse outcomes related to HIV and other STIs. However, change is challenging and will require a commitment to articulating the rationale for and vision of change; to building coalitions for change; to utilizing a strategic approach to implementation; and to assessing and evaluating progress. Key among these is the importance of national leadership in facilitating change, whether through supportive policies, adequate resourcing, providing infrastructure, or coordinating partnership efforts. Efforts to promote sexual health should incorporate proactive strategies to engage political and other influential leaders at the national, state, and local levels to commit to sustained action, and to ensure that supportive and culturally competent policies are instituted, based on the best available evidence. Implementing effective sexual health policies requires a supportive policy context. As sexual health programs are scaled up, the policy framework—laws, regulations, norms—have to be supportive for programs to succeed. Practitioners must commit to working with governmental and nongovernmental partners to identify and provide a supportive environment to implement evidence-based policies related to sexual health.

Implementing a robust sexual health approach will require investments to strengthen the prevention, treatment, and care infrastructure (public and private) needed to provide appropriate sexual health services that are adequately linked to allied and support services, and to provide a seamless interface for clients to address complex health and social needs. Governments will need to ensure that comprehensive sexual health services are available to the public, and that health professionals are trained to provide such services. Other key requirements include commitments to address sexual health across the lifespan and to understanding that age-appropriate needs exist at all levels; and that effective partnerships with communities, service providers and policy-makers will be required to achieve change and to maximize health impact.

Research, evaluation and surveillance are needed to support and optimize national sexual health efforts. Research is needed to develop and assess new prevention approaches that utilize a sexual health framework, and to assess the feasibility and acceptability of such a framework to clients and providers. Research is needed also to understand the best way of integrating related services and approaches and to understand better the benefits and potential

costs of such integration. Improved surveillance will be needed both to monitor individual health outcomes related to sexual health and to assess comorbidities by behavior, socioeconomic status and geographic clustering to better target prevention efforts. Ultimately, a sexual health approach will require the identification of more robust indicators of sexual health, including disease outcomes, risk behaviors, patterns of healthcare access, network characteristics, and societal norms, attitudes and policies. This will enable jurisdictions to both evaluate their health status and to define appropriate goals for optimal sexual health.

Finally, adopting a sexual health approach will require that new and dynamic partnerships be created, with a wider range of constituents outside of the traditional HIV/STI prevention and control field. These partnerships can reinforce the importance of individual and community responsibilities in achieving the goal of creating societies in which individuals, families and communities are encouraged to understand human sexuality and to cultivate sexual health and responsible sexual behavior. While each person is responsible for maintaining one's own sexual health and for protecting the sexual health of others, there are also important dimensions of community responsibility for sexual health in which the social environment provides freedom from sexual violence, coercion, exploitation and discrimination.<sup>73</sup> These multilayered determinants of sexual health suggest that corporations, nonprofit organizations, faith communities, schools and federal agencies must be included in the partnerships to improve sexual health, and that care must be taken to include a more diverse range of constituencies from across the political, religious and social spectra. These strategic partnerships are essential to the broad acceptance and overall effectiveness of a sexual health effort.

### Summary

The urgent, complex, and enduring nature of the global STI epidemics, including HIV infection, suggests that we should not continue doing the same things and expecting different outcomes. Recent additions of biomedical interventions to the prevention toolkit are encouraging, but it is not wise to think that we will ever be able either to treat or to vaccinate our way out of these epidemics entirely without addressing their root causes and social contexts. Rather, what will be required is a fundamental shift in how we conceptualize and speak about sexual behavior, human sexuality, and sexual health, and their importance in our everyday lives. Key to this will be building societies that are committed to the sexual health of all people, in which individuals understand and respect their own sexuality and that of others, and the individual and community responsibilities in achieving optimal sexual health as accepted as valid components of overall health and well-being.<sup>74</sup> This will go a long way towards addressing the stigma, the discrimination, the fear, and the silence that continue to hamper global prevention efforts, prevent national commitment to action, allow complacency within communities, and harm lives around the world.

# Historical Aspects of Sexually Transmitted Infections

James S. Bingham

## 2

### Introduction

Sexually transmitted infections (STIs) have an interesting history and are believed to have existed since earliest times. Their transmission is related to human nature and frailties and they can have devastating effects on the body, on the mind and psyche, and on the ability to procreate. Perceptions about STIs have varied from one society to another and even today, for example, the industrialized world has a relatively enlightened approach to human immunodeficiency virus (HIV) infection, whereas some southern African countries have, at one point, virtually denied their existence.

The recent history of STIs mirrors, to a degree, the development of modern scientific medicine. The advent of microscopy in the late 19th century allowed the identification of the causative organism of gonorrhea and, in the early 20th century, the causative organisms of chancroid and syphilis were identified. The first serological test for any infection, the Wasserman reaction, helped to confirm the presence of syphilis and the first disease-specific modern treatment for an infection, arsphenamine, was developed for syphilis in 1909. Discovery of the bacteriostatic sulfonamides in 1937 by Domagk permitted the first effective treatment for gonorrhea but antimicrobial resistance soon occurred. With manufacture of penicillin, the first bactericidal antibiotic in 1943, both gonorrhea and syphilis became reliably treatable. Resistance to antibiotics, now perceived as a major threat with bacterial infections, has not spared *Neisseria gonorrhoeae* and chromosomal and plasmid-mediated resistance have been identified.

As the science of virology developed in the middle 20th century, other common STIs became more readily recognized, such as genital warts caused by strains of the human papillomavirus (HPV) and genital herpes caused by the herpes simplex virus (HSV). Indeed, the first reliable antiviral agent, acyclovir, was developed to treat genital and oral herpes simplex lesions in the early 1980s. Meanwhile, the science of immunology was developing in the latter half of the 20th century, retroviruses had just been discovered and, in 1983, HIV was identified as the cause of acquired immune deficiency syndrome (AIDS). The immunological basis of this most

devastating of STIs was elucidated and more is now known about HIV than any other virus.

### When did it All Begin?

The origins of the venereal (sexually transmitted) diseases are obscure. Medical and other historians have often suggested that well-known diseases such as syphilis, gonorrhea, chancroid, and lymphogranuloma venereum have existed since earliest times. This may, or may not, be true and some of these individuals may have drawn conclusions from ancient texts and manuscripts which may not be accurate. While the infections certainly exist in *Homo sapiens*, did they occur in the preceding species, *Homo erectus* prior to 150,000 BC? No one knows, but the French philosopher, Voltaire summed it up well when he declared in his *Dictionnaire philosophique* that *Venereal diseases are like the fine arts—it is pointless to ask who invented them*.

In examining the old literature, primary sources are not always available and translations are open to misinterpretation. Clinical observation may have been poor and genital infection was often viewed with distaste. The Chinese may have produced the first description of a sexual infection; Captain Dabry, a French naval officer, made a study of Chinese medical writings dating back to 2500 BC, publishing his findings in 1863.<sup>1</sup> He was able to describe a “corroding ulcer” of the genitals in men and women, which developed within a few days of sexual intercourse, followed by pharyngeal and anal ulceration. It is not possible to know if this might have been syphilis. In 1872, the George Ebers papyrus was revealed, dating back to 1550 BC.<sup>2</sup> It contains a reference to vulvovaginal inflammation which has been loosely ascribed to gonorrhea and it also refers to remedies for lice infestations. Recent studies on the bones of Egyptian mummies, dating from the pre-Dynastic to Byzantine eras have not shown any evidence of bony syphilis, however.

### BIBLICAL REFERENCES

The Christian *Old Testament* is littered with accounts of marital infidelity, prostitution, and descriptions of what might have been

venereal or STIs.<sup>3</sup> One passage, in *Deuteronomy* 28:27, that might refer to secondary syphilis reads as follows:

*The Lord will smite thee with the botch of Egypt, and with the emerods, and with the scab, and with the itch, whereof thou canst not be healed.*

In another passage, Psalms 38:5, 7:

*My wounds stink and are corrupt because of my foolishness ... for my loins are filled with a loathsome disease, and there is no soundness in my flesh.*

Some have suggested that this could represent syphilis but it could just as likely be representative of any other ulcerative condition. The biblical character, Job, was polysymptomatic: he had skin ulcers, loss of hair, foul breath, bone pains, loss of appetite, diarrhea, and fever but despite all this he lived into old age. It is likely that all of this is referring to religious progress rather than to venereal disease.

The other disease, apparently recognized from earliest times is gonorrhea. A widely quoted text from the *Old Testament* is the following from the *Book of Leviticus*, 15:2-12.

*When any man hath a running issue out of his flesh, because of his issue he is unclean. And this shall be his uncleanness in his issue: whether his flesh run with his issue, or his flesh be stopped from his issue, it is his uncleanness.*

It is believed that this passage refers to a discharging condition but the organ or part of the body affected is not specified. If it does mean a urethritis, it could just as easily be nongonococcal as gonococcal in origin. However, the fact that this was likely to be sexually acquired is clear because the text goes on to say ... *And the woman if she has an issue she too ... and she shall be put apart for seven days.*

In the *Book of Numbers* there is an account of the Israelites making war on the Midianites. They were successful and returned with 24,000 women. Moses was not pleased and ordered personal hygiene for every man; the participants were quarantined outside the camp and all the Midianite women *that have known man by lying with him ... to prevent a plague amongst the congregation* were slaughtered. Clearly, Moses understood the epidemiology and its origin in sexual intercourse and he probably recognized that the incubation period too. In a way, he may have been the first recorded contact tracer and was certainly effective!

## GREEK AND ROMAN REFERENCES

Hippocrates (460–377 BC) lived some two centuries after the book of *Deuteronomy* was written. He was an astute observer who was able to describe disorders of micturition, menstruation, and pregnancy. He also referred to *moist ulcers, particularly of the mouth and genitals*. In *De locis affectis* is the following short statement—*No disease has more varied symptoms than strangury. It is most commonly found in youths and old men. In the latter it is more rebellious, but nobody dies of it.* Some believe that this statement refers to gonorrhea but it seems more likely that it

could just as well be referring to cystitis or to urinary obstruction due to stricture, calculi, or prostatic enlargement. Nevertheless, Hippocrates was apparently in no doubt that strangury was the result of indulgence in the pleasures of Venus.

Other Greeks, such as Aristotle and Plato have mentioned gonorrhea in their writings and in Seneca's letters, we discover that Epicurus, the founder of Stoicism's rival philosophy, may have died of the disease. Apparently, at the age of 71 years he developed acute urinary retention and, despite spending the last 2 weeks of his life in a bath, he was unable to relieve himself. Of course, he may have had a renal stone or prostatic enlargement but some say that his death was due to gonorrhea, with the urinary retention presumably being attributed to urethral stricture.

The earliest Latin medical writer, Celsus (25 BC–50 AD) devoted a whole chapter of his *De medicina* to genital diseases. He certainly described ulceration of the glans penis complicating phimosis, retention of urine and its relief by catheterization. Indeed, he was the first person to describe this treatment. He also mentioned growths and gangrene of the penis and he discussed *profusio seminis* in the following words: *There is a fault in the genital region called the shedding of semen. It occurs without sexual desire or erotic dreams in such a way that in time the patient is consumed by wasting.*

Galen (130–200 AD), the "Prince of Physicians," was the most famous Greek physician after Hippocrates and his opinions dominated European medicine until the Renaissance. He certainly described penile ulcers and reported anogenital excrescences which were probably warts. In *De locis affectis* he was the first to use the word gonorrhea to describe a condition that appears to be similar to *profusio seminis*:

*Gonorrhoea is an unwanted excretion of semen which you may also call involuntary; or to be more precise you may say a persistent excretion of semen without erection of the penis.*

Vertue has suggested that these descriptions do not resemble the features of contagious gonococcal urethritis that we recognize today although, they could be representative of chronic nongonococcal urethritis, spermatorrhoea, or even prostatitis.<sup>4</sup> Likewise, Karl Sudhoff (1853–1938 AD) who was the first German professor of the *History of Medicine*, in Leipzig was not convinced that there was definite evidence that syphilis existed in Greek and Roman times and made the following statement ... *The literary proof that syphilis existed in Greece and Rome must, for the present at least, be considered a failure.*<sup>5</sup>

## ARABIC AND OTHER REFERENCES

Rome was sacked by the Barbarians in 410 AD and the European civilization descended into the Dark Ages. By 500 AD the western Empire had disappeared and many doctors fled to the eastern Empire, centered in Constantinople. The Graeco-Roman tradition was maintained but ideas stagnated in Byzantine medicine. If medicine was not flourishing in Byzantium it was active in Islam. Arabic culture reached its zenith in the 9th and 10th centuries in Baghdad which was a particular center for

mathematics and science. The ancient medical writings were translated into Arabic and the writings of Islamic physicians became the standard texts for the Western world. Again, they do not appear to have described a disease resembling syphilis but were almost certainly seeing patients with gonorrhea. The Persian, Rhazes (860–932 AD), gave a full account of urethral discharge and its treatment by irrigation. He appears to have been familiar with urethral stricture and emphasized the importance of catheterization if there was retention of urine. Ibn Sina (Avicenna; 980–1037 AD), a notable teacher, described the treatment of acute urethritis by irrigating the urethra through a silver syringe. He is said to have further enhanced treatment by inserting a louse, sometimes referred to as a bug or a flea, into the fossa navicularis in difficult cases.

Surprisingly, there is little to be gleaned from the Chinese, Japanese, Assyrian, or Hindu texts. In the 5th century, however, a Hindu physician, Sushruta, devoted a chapter in his *Diseases of the Urinary Passages* to dysuria but it would seem that he did not relate this to sexual acquisition. This is surprising as he was well-acquainted with the treatment of malaria, plague, tuberculosis, and smallpox. Other Hindu physicians certainly used urethral irrigations too. In the 9th century, a School of Medicine was founded at Salerno in southern Italy. Teaching there was based on the Graeco-Roman and Arabian principles, and particularly on the writings and thinking of Avicenna. Urination after intercourse to protect the urethra was one of the aphorisms of the day. In England, John of Arderne (1306–1390 AD) who had been a physician to Richard II, also mentioned urethral irrigation. This seems to have been a little more sophisticated as he advised ... *take the milk of a woman, a little sugar, oil of violets, and barley water and administer it with a syringe.*

## THE MIDDLE AGES (1000–1400 AD)

In the Middle Ages, gonorrhea was certainly described but also there were many references to genital ulceration. The Italian surgeon, Theodoric of Cervia (1205–1298 AD) wrote a description ... *of the corruptions that appear in men around the prepuce on account of coitus with an impure woman.* His contemporary William of Saliceto (1210–1280 AD) described ... *ulcers and pustules that arise because contact with impure women is followed by the retention of filth or venomous material between the glans and prepuce.* There are many such writings and the nature of what they were describing is unknown although the possible diagnosis might include chancroid, genital herpes, erosive balanitis, and phagedenic ulceration. John of Arderne described this as follows:

*The man's yard began to swell after coit, due to the falling of his own sperm, whereof he suffered great grievousness of burning and aching as men do when they are so hurt.*<sup>6</sup> He managed this condition by cutting away all the dead flesh with a razor and applying quicklime, apparently with success.

It is noticeable in all these writings that little attention is paid to the treatment of women with genital infections. This may be because they were not highly regarded in the community and

therefore, did not receive medical attention. Or, they may have been regarded as corrupt and promiscuous and therefore not deserving of attention. Anyway, by the time of the Renaissance, some doctors were certainly reluctant to treat anyone with venereal diseases, and in London, a regulation in 1430 was passed which excluded patients with venereal diseases from public hospitals.

## Syphilis and Gonorrhea

### SYPHILIS

Europe was shocked by the appearance of syphilis in 1493, believed to have been brought back to Europe, from the New World, by Columbus's sailors. By the following year there were cases across the continent but an epidemic arose in Naples where the French King, Charles VIII, was besieging the city assisted by mercenaries, including some from Spain. Naples was defended by King Alphonso II, also with the help of some Spanish mercenaries. Both armies had camp followers and the nature of warfare at the time allowed these people to pass from one camp to the other. Such was the level of debauchery and prostitution that, while Charles was at first successful in capturing the city, an Italian alliance was formed and this combined with an outbreak of the new disease, resulted in the lifting of the siege. The French called it the Italian disease and the Italians, the French disease. Charles discharged his soldiers who returned to their homes across Europe spreading the disease as they went. Charles, himself, died of it in 1497.

By 1495 it had reached France, Germany and Switzerland, England and Scotland by 1497, India in 1498, and China in 1505. It was, seemingly, a much more virulent disease than that which we recognize today and a stream of publications soon appeared, mainly from Italy and Spain. The most famous was the poem, *Syphilis sive Morbus Gallicus*, by Girolamo Fracastoro (1498–1553 AD) (Fig. 2.1), published in 1530, in which he gave a clinical description and then described treatment with mercury and guaiacum, a South American/Caribbean wood resin. He recounted the tale of a shepherd, Syphilus, who defended Apollo and was punished with a foul disease. It was translated into English verse by Nahum Tate in 1686 AD and the term syphilis was first used in an English medical text in 1717 AD when Daniel Turner published his book *Syphilis: a Practical Dissertation on the Venereal Diseases*.

There was little clinical advance in the 16th century although Fallopius described the indurated primary sore of syphilis and was able to differentiate between condylomata lata and condylomata acuminata (genital warts). In the 17th century cardiovascular syphilis was described (Lancisi and Hermann Boerhaave). The French physician Jean Astruc (1684–1766 AD) summarized the body of knowledge in *De Morbus venereis* (1736 AD) and took the view that syphilis had been introduced to Europe and beyond by Columbus's sailors upon their return from Hispaniola (Haiti). Lazar houses, or locks, had existed across Europe for the treatment of leprosy, which may have been confused with syphilis. The UK

**Fig. 2.1:** Girolamo Fracastoro (1498–1553 AD). *Source:* Wellcome trust photographic library (Reproduced with permission).

had numerous such institutions and most European cities had similar arrangements.

### WERE SYPHILIS AND GONORRHEA MANIFESTATIONS OF THE SAME DISEASE?

Early writers, such as de Vigo and Fernel, regarded syphilis and gonorrhea as different diseases but by the 16th century there was doubt about this. The Swiss physician, Paracelsus (1493–1541 AD), considered the two diseases to be one and the same and called syphilis “French gonorrhea.” Ambroise Paré (1510–1590 AD), the distinguished French surgeon and Thomas Sydenham (1624–1689 AD) as well as Jean Astruc believed that the two diseases were one and the same and were, therefore, regarded as *monists*.<sup>7</sup> By the mid 18th century some physicians were considering a separation between syphilis and gonorrhea once more. Hermann Boerhaave in his book on *lues venereal*<sup>8</sup> differentiated between the two diseases suggesting that gonorrhea was nothing more than a purulent catarrh, rather like that occurring with the common cold. There were other notable *dualists* such as Gerhard van Swieten (1700–1772 AD) in Austria.

John Hunter (1728–1793 AD) (Fig. 2.2), a Scottish surgeon practicing in London wrote a treatise on the *venereal disease* in 1786.<sup>9</sup> In this he made several major errors of interpretation. He believed that there was only one “venereal poison” and if this fell on a mucosal surface it would cause gonorrhea but if it fell on the skin it would cause a chancre and, if it was absorbed into the circulation it would cause constitutional syphilis. It was said that he carried out an experiment in 1767 in which he inoculated a recipient’s glans and prepuce with material from a patient with gonorrhea. Some said that the recipient was Hunter himself but

it is more likely that the subject of the experiment was a patient, reflecting the ethics of the day. A chancre appeared 10 days later with associated inguinal lymph gland enlargement, ulceration of the tonsils and a generalized skin rash. The whole illness lasted for some 3 years. Today, it has been interpreted that the donor had a double infection but the experiment convinced Hunter that he had been able to produce syphilis by the inoculation of gonorrheal pus.

Because of Hunter’s prestige, this view persisted until Benjamin Bell (1749–1805 AD), another Scottish surgeon based in Edinburgh, wrote his *Treatise on Gonorrhoea Virulenta and Lues Venerea* in 1793. In summary, he felt that the signs and symptoms of gonorrhea and syphilis were different. He said that gonorrhea did not progress to syphilis and that if they occurred together this could be explained by either having contracted both conditions at the same time or one after the other. He said that diseases in sex partners matched the diseases in index cases and, in Scotland, he said that he had never seen a patient with syphilis develop gonorrhea. Also, he noted that the treatment for syphilis with mercury was ineffective against gonorrhea.

Bell’s views were subsequently supported by the American-born Frenchman, Philippe Ricord (1800–1889 AD) (Fig. 2.3). He conducted a series of experiments where he inoculated pus from urethral discharge, genital ulcer or draining bubo into the patient’s own thigh and, covering it with a watch glass, examined the site daily for the development of lesions. He performed more than 2,500 of these inoculations and he published the results of his experiments in his *Traité pratique des Maladies Vénériennes*.<sup>10</sup> He concluded that an ulcerated chancre, or its resultant bubo, will always reproduce a chancre when reinoculated, that reinoculation of material from ulcers of secondary syphilis will not produce a

**Fig. 2.2:** John Hunter (1728–1793 AD). *Source:* Wellcome trust photographic library (Reproduced with permission).

**Fig. 2.3:** Philippe Ricord (1800–1889 AD). *Source:* Wellcome trust photographic library (Reproduced with permission).

chancere and reinoculation of the pus of blennorrhagia (gonorrhea) will not induce a chancre. Thus, he understood that syphilis had one cause and that gonorrhea was not caused by syphilis. He also thought that secondary syphilis was not contagious but this of course was a misinterpretation. While he maintained that view for many years, by 1858 he had to make a humiliating public announcement that he had been wrong.<sup>11</sup> Nevertheless, he proposed a simple scheme to classify syphilis, which was as follows:

- A primary lesion, a chancre, the first manifestation of an infection.
- Secondary lesions, resulting from that infection.
- Tertiary lesions (gummas) which rarely appear before the end of the 6 months but whose development could be delayed for many years.<sup>12</sup>

Experimentation continued and was not successful in lower animals. Eventually, primates were inoculated, and in particular the chimpanzee. One of the main researchers in this area was Albert Neisser who discovered the gonococcus in 1879. He found that monkeys did not thrive in Breslau, where he lived, and moved his laboratories to Batavia (now Jakarta) in Java. He stayed there for some years and produced the most comprehensive account of experimental syphilis ever published.<sup>13</sup> Within it he had established the incubation period of syphilis and confirmed the contagious nature of secondary syphilis.

## Identification of Causative Organisms of STIs and Confirmation of their Presence by Serological Means

### TRICHOMONAS VAGINALIS

There had been myths in the ancient world that human diseases might have been caused by small living creatures and this was

revived, as an idea, by Fracastoro in his *On Contagion*, in 1546. But with the advent of the microscope the French microscopist Alexandre Donné (1801–1878 AD), made a number of observations: he discovered platelets, noted the leukocytosis of leukemia and, in 1836, identified a flagellate protozoa, which was subsequently named *Trichomonas vaginalis*.<sup>14</sup> There was little interest in the organism, which was believed to be a harmless commensal. However, in 1894, *T. vaginalis* was found in the male urinary tract and it was suggested that it might be sexually transmissible. And it was not until the 1930s that the concept of sexual transmission became established.

### NEISSERIA GONORRHOEAE

As microscopy improved and because it was felt that gonorrhea might have a bacterial cause, effort was made to identify the causative organism. This was finally achieved in 1879 by Albert Ludwig Sigismund Neisser, working in Breslau which was then in Prussia but is now in Poland. He was using a Zeiss microscope with an oil immersion system and the new Abbe condenser. He was examining smears, stained with methyl violet by Koch's technique from 35 men and 9 women with purulent urethritis and 2 patients with acute ophthalmia. He was able to identify the small organisms as follows .... *They are seldom seen as solitary individuals; almost always they appear as micrococci packed close together so as to give the observer the impression of a single organism shaped like a figure of eight.* These, of course, were the gonococcal diplococci and Neisser's name was given to the genus. While he went on to culture the organisms on a meat extract-gelatin medium there is some doubt as to whether or not the organisms cultivated were actually gonococci. Attempts at inoculation did not produce clinical disease and so Koch's postulates were not satisfied. However, when the urethra of a man was inoculated in 1883 by Max Bockhart, classic gonorrhea developed after 3 days.

### TREPONEMA PALLIDUM

In 1905, at the Institute of Zoology, University of Berlin, an assistant claimed to have found a flagellate protozoon in syphilitic lesions. Other workers at the Institute treated this with some skepticism and it was decided to undertake further work which was entrusted to Fritz Schaudinn (1871–1906 AD) and Eric Hoffmann (1868–1959 AD). Using a Zeiss microscope with an apochromatic objective, Schaudinn examined a fresh preparation which Hoffmann had prepared from an eroded vulval papule in a woman with secondary syphilis. Several pale spiral organisms were seen which rotated about their long axis, and moved backwards and forward undergoing movements of flexion or angulation. They called the organism *Spirochaeta pallida* and subsequently found it in both fresh and Giemsa stained preparations from 11 patients with early syphilis. They were able to differentiate the pale finely coiled *Spirochaeta pallidum* and the dark, thicker *Spirochaeta refringens* which were often present in many nonsyphilitic specimens. A preliminary report was written up in April 1905.<sup>16</sup> Treponemes were identified

in the brain of patients with general paresis and tabes dorsalis by Hideyo Noguchi (1876–1928 AD), a Japanese pathologist working in New York. He was using tissue impregnated with silver nitrate.<sup>17</sup> For some years, a clinical resemblance had been noted between syphilis and yaws and, in 1905, Aldo Castellani (1877–1971 AD) working in Sri Lanka, found the spirochaete *Treponema pertenue* by microscopy of wet and stained specimens from patients with yaws.<sup>18</sup>

## Wassermann Reaction

The complement fixation reaction had been devised by Jules Bordet and Octave Gengou, working at the Pasteur Institute in Paris, in 1901. When Neisser returned from Java in 1906, he went to see his old friend August Paul von Wassermann (1896–1925 AD) (Fig. 2.4). They agreed that there was no satisfactory serological test for syphilis and they decided to apply the complement fixation technique to the disease. Neisser agreed to supply extracts of syphilitic organs from apes and humans to use as antigens and Wassermann was to undertake the laboratory work. In fact, he was assisted by Neisser's assistants, Schucht and Bruck. They made rapid progress and the first results were published in 1906.<sup>19</sup> Wassermann was fortunate that he published first since Laszlo Detre (1875–1939 AD), a Hungarian physician, had carried out similar work and published his results a few weeks later. The test was often abbreviated to the “WR” and because the complement fixation test was time consuming, a simpler flocculation test was devised, originally in 1921, by Reuben Kahn in America. By 1941 the serologically reactive substances, cardiolipin and

**Fig. 2.4:** August Paul von Wassermann (1896–1925 AD). Source: Wellcome trust photographic library (Reproduced with permission).

lecithin were isolated from the crude alcoholic extract of beef heart which had previously been used as the antigen. A more modern test that was developed using this substance became known as the Venereal Disease Research Laboratory (VDRL) test. Of course, it had been recognized from early experience that the WR could sometimes give false positive results in people without syphilis and it became clear that a specific serological test was required. The first of these to be introduced by Robert Nelson and Manfred Mayer at the Johns Hopkins School of Hygiene and Public Health in 1949 was the *Treponema pallidum* immobilization (TPI) test. Subsequent newer specific tests are well-known to current practicing physicians.

## CHANCROID

It had been recognized for a long time that not all genital ulceration was necessarily due to syphilis but even famous physicians, such as Ricord, failed to realize that chancroid was a specific cause of genital ulceration. This situation was rectified by one of Ricord's pupils, Léon Bassereau (1810–1887 AD). He recorded that indurated chancres were usually followed by constitutional symptoms and signs while nonindurated chancres were a purely local affliction. He then went on by means of “confrontation”—what we would call today contact tracing, to demonstrate that each of these lesions was associated with a similar lesion in the sex partners of the index case.<sup>20</sup> His theory was supported by Joseph Rollet (1824–1894 AD), another French syphilologist who accepted that some cases were hard to classify. Chancroidal ulceration was repeatedly reinoculable in the same individual whereas a syphilitic chancre was not. Of course, he said, a mixed chancre could exist due to simultaneous infection by the causative organisms of the two diseases. Ricord was finally convinced by this and supported the views of his young colleagues.

The organism causing chancroid was finally identified by Augusto Ducrey (1860–1940 AD) who was working in Naples when he made his discovery. He had noticed that microscopic examination of pus from chancroidal lesions showed many different microorganisms. He inoculated some of this material into each patient's own forearm and the resulting ulcer was reinoculated and by doing so he was able to passage the bacteria many times. This allowed the contaminants to die out and he was thus able to describe a short rod with rounded ends which later became known, after him, as *Haemophilus ducreyi*.<sup>21</sup>

## DONOVANOSIS

This type of anogenital ulceration, caused by bacteria to be identified was first described by Kenneth MacLeod (1844–1922 AD) who was working in the Indian Medical Service, in the days of the British Raj. His description of the condition was contained in a summary of the operations performed in his department in Calcutta during 1881.<sup>22</sup> It fell to an Irish colleague in the service, Charles Donovan (1863–1951 AD) to describe the causative organism. In 1905 he identified intracellular bodies which later became famous as “Donovan bodies” in stained tissue smears

from patients with donovanosis which he described under the heading *Ulcerating granuloma of the pudenda*.<sup>23</sup> Eventually, these were shown to be capsulated gram-negative bacteria but it was some years before it was possible to propagate them in the yolk sac of fertilized hens' eggs.

## CHLAMYDIAE

When Neisser went to Java in 1903 to study experimental syphilis in monkeys, he had among his team two young men, Ludwig Halberstaedter (1876–1949 AD) and Stanislaus von Prowazek (1875–1915 AD). While in Java they became interested in trachoma and, while Neisser forbade them from undertaking research on the disease, they went ahead and did it anyway and were able to identify inclusion bodies in conjunctival scrapings from orangutans which they had infected with scrapings from patients with trachoma. They published their work in 1907.<sup>24</sup> The findings were confirmed within a few years by other workers who reported similar inclusions in conjunctival cells from some infants with nongonococcal ophthalmia and in cervical cells from their mothers.<sup>25</sup> Halberstaedter and von Prowazek suggested the name Chlamydozoa for the organisms, derived from the Greek word *chlamys*, a cloak. They believed that they might be protozoa but when they found that they could not pass through bacteria-proof filters they regarded them as viruses, incorrectly as it turned out. A few years earlier, in 1904, Ludwig Waelsch in Prague described a form of nongonococcal urethritis which had an incubation period of some 10–14 days but ran a mild and protracted course. Some years later the urethroscopic features of this “Waelsch urethritis” was described as being similar to nodules in trachoma. Subsequently, in the 1960s, Moulder showed that chlamydiae are intracellular bacteria and he introduced the current classification of a family Chlamydiaceae and the genus *Chlamydia* with two species *C. psittaci* and *C. trachomatis*, the latter comprising ocular, genital and lymphogranuloma venereum strains.<sup>26</sup> With the development of yolk sac culture of *Chlamydia* in the 1950s, Dunlop and colleagues were able to demonstrate the presence of *Chlamydia* in nongonococcal genital infection.<sup>27</sup>

## VIRUSES

### Genital Herpes

While the term “herpes” has probably been used for a long time, Jean Astruc is usually given credit for the first full description which appeared in his *De Morbis Veneris*, published in 1736.<sup>28</sup> He mentioned the common sites affected and the small blisters. Subsequently, dermatologists classified vesicular rashes and included herpes within that classification. It was Jean Louis Alibert (1766–1837 AD) who first described the condition in women, as well as men thereby suggesting the possibility of sexual transmission.<sup>29</sup> The natural history of the condition was described by Francis Booth Greenough (1837–1904 AD) at the Harvard Medical School who had read a paper to the American Dermatologic Association in 1880 on herpes

progenitalis.<sup>30</sup> He said that the disease was not serious, that it had a tendency to relapse and produce mental anxiety. It was the German dermatologist Paul Gerson Unna (1850–1929 AD) who concluded that women were just as susceptible to herpes as men. Finally, the American virologist Ernest William Goodpasture (1886–1960 AD) established the principle of latency of the herpes viruses.<sup>31</sup>

### Genital Papillomavirus Infection

Penile and anal warts had been known from ancient times and are extensively mentioned in Greek and Roman writings. They were commonly referred to using the word *figus* (a fig) and the term *Condyloma acuminatum* began to be used towards the end of the 19th century. At first there were descriptions in men only but both John Hunter and Benjamin Bell described their presence on the vulva in females. Various organisms were spuriously identified in the lesions and they were thought to be related to skin warts. There was considerable controversy as to whether or not they could be sexually transmitted with the Frenchman Jourdan stating in 1826 that they could occur in both sex partners.<sup>32</sup> Despite considerable doubt by most observers, thereafter, by the 1920s and 30s many venereologists had concluded that genital warts were sexually transmitted. The fact that skin warts were caused by viruses had been demonstrated early in the 20th century when inoculation of cell-free filtrates of excised warts resulted in transmission of the disease. Subsequently prostitutes were persuaded to permit inoculation of the genital area and, in one disgraceful experiment, a virgin was inoculated. Nevertheless, many dermatologists refused to believe that genital warts were transmitted sexually but the matter was eventually resolved by Barrett and his colleagues in 1954. They were able to study a large number of soldiers returning from the Korean war who had developed genital warts. They had the opportunity to examine the wives, some of whom developed lesions after their husbands' return. The conclusion was that the condition was highly contagious and should be classed as a venereal disease.<sup>33</sup>

### Human Immunodeficiency Virus (HIV)

In June 1981, an alarming report appeared in the pages of the Morbidity and Mortality Weekly Report of the United States Centers for Disease Control in which were described five cases of *Pneumocystis carinii* pneumonia occurring in previously healthy men in the Los Angeles area.<sup>34</sup> In the succeeding months similar cases were reported from other cities including outbreaks of other immune deficiency associated conditions such as Kaposi's sarcoma, mucosal candidiasis, disseminated cytomegalovirus infection, and chronic HSV ulceration. There was evidence of T-lymphocyte dysfunction and, in particular, there was marked depletion of the CD4+ T-lymphocytes. The initial cases were occurring in homosexual men but soon other cases appeared in intravenous drug users and in Haitians.

Because of the practice of voodoo in that country the idea that the problem might be zoonosis was entertained. However,

retroviruses had been discovered some years earlier and one of them, feline leukemia virus was known to induce immune deficiency. Because of this, retrovirologists began to look for another member of the family and, in 1983 Luc Montagnier and his group in Paris managed to isolate a retrovirus from a lymph node which they called lymphadenopathy-associated virus (LAV).<sup>35</sup> This was somewhat ignored until the following year when another group, led by Robert Gallo at the National Cancer Institute in Bethesda (USA), confirmed the isolation and considerably expanded the evidence linking this retrovirus which they called the human T-lymphotropic virus type 3 to the immunodeficiency syndrome. The virus was subsequently renamed the human immunodeficiency virus type 1 (HIV-1) and in 1986, a second immunodeficiency virus (HIV-2) was isolated from West Africa.<sup>36</sup>

But when did the virus enter the human host? Possibly, more than a million years ago a chimpanzee was infected by viruses coming from two different monkey species. This resulted in a recombination event producing a virulent virus that wiped out 90% of the chimpanzee population over the next 100,000 years. It is estimated that around 1900, in Africa, the first transmission events of the virus to humans occurred; over the next 80 years the virus produced mini-epidemics that flared and faded until, in the late 1970s, the epidemic gained momentum and rapidly assumed the proportion of a pandemic, spreading around the sub-Saharan part of the continent and exiting Africa to affect other parts of the world.<sup>37</sup>

The arrival of this new viral infection has had a profound effect on modern life. First of all there was fear, stigmatization of homosexual men and realization that the virus could be transmitted in blood and its products, as well as in other tissues resulting in expensive law suits against some governments who may not have moved quickly enough to screen the blood supply. As an STI, it is found in the young predominantly and, in some countries, such as in many African states, the educated élite have been decimated with devastating potential effects on economies. An explosion of scientific endeavor has taken place and more is now known about HIV than any other virus. The pathogenesis has been considerably elucidated and new classes of cytokines discovered. Treatment has advanced by leaps and bounds and but little progress is being made in vaccine development.

Most professionals strongly advised against sexual promiscuity or, at the very least, advocated the use of barrier contraception, and some governments engaged in national awareness advertising. In some industrialized countries this has had the effect of reducing the incidence of STIs, particularly among high risk groups.<sup>38</sup> It was given further impetus when it was realized that other STIs could facilitate HIV transmission.<sup>39</sup> However, for ordinary practicing venereologists it has been a fascinating experience dealing with the complex medical problems that people with HIV infection present. Indeed, with its multisystem dysfunction, it has been viewed by some as the new syphilis. Indeed, Sir William Osler's old aphorism ... "He who knows syphilis knows medicine" could equally apply to HIV infection.

## Hepatitis B Virus

The hepatitis B virus was identified by David Dane at The Middlesex Hospital in London, in the early 1970s (the Dane particle). At about the same time, when the serology of hepatitis B was being unraveled, it was soon noticed that acute hepatitis B was occurring among sexual contacts of HbsAg carriers. While there was an increased prevalence among individuals attending STI clinics, the most striking serological evidence relating transmission of the virus to sexual practices was found in homosexual men having anal intercourse. Because of this risk, in industrialized countries, it is normal practice to offer hepatitis B vaccination to such individuals.

## ENTERIC BACTERIAL AND VIRAL INFECTIONS

The modern physician practicing in the field of STIs, in the industrialized world, is *au fait* with the infections particular to those using the anus as a sexual organ. Certainly, in the "Swinging Sixties" in London and elsewhere, 20% of gonorrhea and 70% of early syphilis was acquired homosexually. But it was soon realized, in the 1970s, that a number of enteric infections were more prevalent in this group too, transmitted by the feco-oral route through the practice of oro-anal contact—"rimming". These included *Salmonella*, *Shigella*, *Campylobacter* spp, as well as *Giardia lamblia*, *Entamoeba histolytica*, and hepatitis A,<sup>40</sup> sometimes collectively known as the "gay bowel syndrome."<sup>41</sup>

## Important Studies

It was realized that not all those infected with syphilis went on to develop the late forms of the disease. In order to determine more accurately what the spectrum of outcomes was, a prospective study was set up by the Norwegian syphilologist, Caesar Boeck (1845–1913 AD). He did so because he wondered if the patients would not do just as well if they did not have the unpleasant and somewhat ineffective treatments then available, mainly with mercury. He collected patients between 1891 and 1910 and his successor at the Oslo Dermatological Center, Bruusgaard, reassessed them in 1929 based on clinical examination and autopsy findings. The data were further analyzed by Gjestland in 1955.<sup>42</sup> The findings revealed that about a quarter of the untreated patients had at least one infectious relapse. Gummatous disease occurred in 15% of patients, usually within the first 15 years; cardiovascular disease developed in 14% of the men and 8% of the women, while neurosyphilis developed in 9% of the men and 5% of the women. Overall, 30% of the patients developed some type of late complication. This work is usually known as the Oslo Study.

More recently the US Public Health Service organized a study at Tuskegee, Alabama in 1932 and continued it for 40 years until 1972. All the patients were African-Americans and, while those with early syphilis were treated with arsenicals, the remainder were left untreated. The results of follow-up examinations were similar to those reported in the Oslo Study.<sup>43</sup> The study, by the

time it stopped in 1972, was considered as a national scandal as informed consent had not been obtained and the whole study was perceived as racist.<sup>44</sup> This work is generally referred to as the Tuskegee study.

After Tuskegee, one would have thought that such unethical research could never happen again. But some believe that it has with individuals in sub-Saharan Africa being tested, in large internationally sponsored studies, for HIV infection and not being informed of positive results, allowing unwitting transmission of infection to sexual partners and offspring.<sup>45</sup> And there has been a general reluctance to accept that unsafe medical injections could be responsible for a significant number of new infections.<sup>46</sup> There are a number of reasons for thinking this including that the HIV prevalence in children is too great to be explained by vertical transmission alone.

## Some Early Treatments

### SYPHILIS

There has been a huge variety of treatments recommended for syphilis prior to the advent of penicillin in 1943. Many were exceptionally unpleasant for the patient and, mostly, they did not affect a cure. Hilaire Belloc in his *Cautionary Tales* summed it up well:

*Physicians of the utmost fame  
Were called at once; but when they came  
They answered, as they took their fees,  
There is no cure for this disease.*

One of the first treatments was topical mercury, advocated by Celsus (25 BC–50 AD), the earliest Latin medical writer. He advised its use in new diseases as it had been useful in some skin conditions. Later, practitioners thought of it because of syphilitic skin eruptions often resembled other skin diseases. It was usually applied with a spatula, a process known as inunction. It might be continued for some 3–4 weeks. Unfortunately, there were many side effects, major among them being excess salivation and mucosal ulceration. This method was certainly used during the early European syphilis epidemic, as was also a wood extract from the West Indies (where the disease was said to have originated) – guaiacum.<sup>47</sup> This was probably no more than a sudorific and not as effective as mercury. Oral mercury was introduced by Philip Aureolus Bombastos von Hohenheim (1493–1541 AD), also known as Paracelsus (Fig. 2.5). The first preparation used was mercuric oxide—“red precipitate” or “angelical powder.” Later, metallic mercury was preferred – “blue mass” and this was the preparation used by Paracelsus. Other mercuric preparations were also used. Heat was thought to be an adjuvant to therapy and sweat rooms or bagnios were often employed. These preparations were difficult to take and a new form – the “blue pill” which was a mixture of mercury, confection of roses and powdered liquorice was used and there was even a preparation with brandy.

By the 19th century inunctions were revived in Vienna by Karl von Sigmund and later, in 1861, Ferdinand von Hebra, also

**Fig. 2.5:** Philip Aureolus Bombastos von Hohenheim, also known as Paracelsus (1493–1541 AD). *Source:* Welcome trust photographic library (Reproduced with permission).

in Vienna introduced mercury by injection. It was initially given intravenously but was later delivered by intramuscular injection. The timing and duration of treatment were discussed endlessly.

Iodides were first used in 1821 by Johann Christian Martini of Lübeck. However, the pharmacokinetics of this form of treatment were studied in Dublin by William Wallace<sup>48</sup> and they were used along with mercury and, in the 20th century, with arsenicals up until the advent of bismuth therapy in the 1920s. Of course, there was discussion about how these medications should be delivered, temporarily, and under the influence of Fournier in Paris, courses of mercury were used alternating with iodides for some 3–4 years and further courses could be extended twice a year until 10 years had elapsed. This was sometimes known as the Aachen treatment.<sup>49</sup>

In Germany, the distinguished researcher, Paul Ehrlich (1854–1915 AD) (Fig. 2.6) and his Japanese coworker Sahachiro Hata, were working on aniline dyes, particularly in relation to trypanosomiasis. They conducted a series of experiments and in experiment “606” the new substance arsphenamine or Salvarsan was identified. This was given intravenously and was found to be extremely effective in early infectious syphilis.<sup>50</sup> Originally, two or three injections were given with or without mercury and a number of trials were carried out by other workers including Albert Neisser. Ehrlich and Hata continued their experiments and in experiment “914” neosalvarsan was identified which could be given intramuscularly rather than intravenously. Newer arsenicals were subsequently introduced but had little real advantage over the originals.

In 1921, in Paris, Sazerac and Levaditi introduced bismuth.<sup>51</sup> This was given as intramuscular injections of sodium or potassium bismuth tartrate. It had an action intermediate between the arsenicals and mercury but, with its arrival, mercury therapy was abandoned and bismuth was given along with the arsenicals as

**Fig. 2.6:** Paul Ehrlich (1854–1915 AD). *Source:* Welcome trust photographic library (Reproduced with permission).

the treatment of choice. There were few side effects with this apart from blue discoloration of the gums.

However, while these treatments seemed to be helpful in early infectious syphilis they were not so effective against the late forms such as cardiovascular and neurosyphilis. Working in Vienna, the neurologist and psychiatrist Julius Wagner von Jauregg introduced fever therapy which he initially produced by using tuberculin and typhoid vaccine, particularly in cases of general paresis. In 1917, however, he introduced tertian malaria as a controllable source of fever with 10 febrile episodes being permitted before terminating them with quinine. This produced approximately a 50% improvement and von Jauregg was awarded the Nobel prize in 1927 for this advance.<sup>52</sup> In America, sophisticated “hot boxes” were invented, known as hypertherms, the most famous version being the Kettering hypertherm.

These treatments continued to be used until the early 1950s, along with penicillin.

In 1943, after penicillin had finally been manufactured through the work of Fleming, Florey and Chain, John Mahoney in New York in 1943, first used penicillin in the treatment of syphilis with dramatic effect,<sup>53</sup> and it has remained the treatment of choice ever since.

## GONORRHEA

An early treatment for urethral gonorrhea was a local astringent such as zinc sulfate. This was regarded as being somewhat irritating and silver nitrate, one of the new silver protein preparations was being used by the time of Neisser. However, urethral irrigations had been used since early times and irrigation with potassium permanganate was introduced by Weiss in 1880. This was the

solution used by most practitioners up until the advent of the antibiotic era. Irrigation apparatus became quite sophisticated and one version, designed by the American urologist Ferdinand Valentine, was used throughout the world for more than half a century.<sup>54</sup> The head of pressure advocated varied from physician to physician but too high a head often caused flushing of the infection higher up the urinary tract to the seminal vesicles, the prostate gland and the epididymis. Where urethral stricture occurred, usually in the posterior urethra, then urethral dilators could be used to relieve the stricture or sometimes gum elastic bougies could be used by the patients themselves. Progress with treatment was often assessed by urethroscopy and, in complicated cases, fever therapy was also used sometimes.

Gonococcal infection in the female was generally not so actively managed and was often left to run its course. Often complete resolution could occur but complicated gonorrhea with pelvic infection was a possible outcome. At one stage the vulva and vagina would be cleaned and the ducts of the accessory glands might be treated with a silver salt, mercurochrome, or acriflavine. Some practitioners irrigated the urethra with potassium permanganate and others cauterized the cervix with silver nitrate. Some even irrigated the uterine cavity through a cervical catheter and one can only imagine the consequences of such treatment.

Gonococcal vaccines were introduced at the time of the First World War and were generally reserved for the more complicated cases. Adequate treatment for gonorrhea did not emerge until Gerhard Domagk (1895–1964 AD) introduced sulfonamides in 1937.<sup>55</sup> Unfortunately, the gonococcus became resistant to this group of drugs very quickly and, by the time penicillin was introduced,<sup>56</sup> the use of sulfonamides had been virtually abandoned.

Of course in the 19th century, in many parts of the world, only a few had access to modern methods of treatment so, for instance in India, there was extensive use of Ayurvedic treatment with traditional medicines.

## Attempts at Control

The steps that Moses took to limit the spread of STIs, in Biblical times, have already been mentioned in this chapter, and are probably one of the earliest accounts of such activities. During the Middle Ages in Europe, efforts were made to limit the spread of venereal diseases. For instance, in the Borough of Southwark in London, brothel keepers were forbidden from keeping any woman believed to be infected<sup>57</sup> and in Edinburgh, in 1497, those with syphilis were compelled to go to an adjacent off-shore island, on pain of being branded on the cheek.<sup>58</sup>

## SOME EFFORTS IN THE UNITED KINGDOM

The incidence of these infections was particularly high in the military and probably interfered with their efficiency. While the French provided licensed brothels for their troops, where the prostitutes were examined regularly, this did not occur

in most other countries. Thus, politicians were tempted to enact legislation to subject prostitutes to compulsory medical examinations. In England, this legislation was in the form of a series of Contagious Diseases Acts in the 1860s. There was a public outcry from women's groups and, despite the contrary opinion of the medical profession, the Acts were repealed in the 1880s. Further, legislation in the form of the Notification of Diseases Act (1889) was passed, which allowed the authorities to impose restrictions on individuals suffering from certain infectious diseases. This time, the medical profession opposed including the venereologists among these as they thought that compulsory notification might lead to concealment of the infection, and thus defeat the object of the legislation. By the beginning of the 20th century in Europe, where there was some idea of the extent of the problem by the counting of cases, venereal diseases were considered to be a major health problem. In the United Kingdom, a Royal Commission was set up in 1913 to investigate and make recommendations. This it did in 1916, in the middle of the First World War. The report was extremely enlightening and proposed the provision by each local authority of a facility to treat venereal diseases, which was to be confidential, free and provided by doctors only, to prevent quacks for practicing in this arena. The Venereal Diseases Regulations were issued, based on this advice, in 1916 and have been continued in subsequent legislation ever since.

## THE FIRST WORLD WAR

During the First World War, the incidence of venereal diseases increased dramatically and soldiers, as they have always done, made liberal use of prostitutes. They were advised to wash the genitals with soap and water as soon as possible after intercourse and then irrigate the urethra with potassium permanganate solution (known by the troops as "*pinky panky*"). Thereafter, the advice was to apply calomel ointment to the whole area and a tube of argyrol to the urethra. This could all be accomplished in "*venereal ablution rooms*" provided by the Army. Eventually, at least for the British Forces, French brothels were placed out of bounds and a regulation was issued (no. 40D of the Defence of the Role Act) that made it a criminal offence for a woman with a venereal infection to solicit or have sex with any member of His Majesty's forces. This was bound to be largely ignored for obvious reasons.

When the United States entered the war in April 1917, the medical authorities in the US Army were keen to control venereal infections. They were impressed by the aggressive control policy of the New Zealand Expeditionary Force where there was a program of frequent medical examination of the soldiers for signs of infection, the issue of condoms and the provision of postcoital prophylaxis. Soldiers were required to attend prophylactic stations not more than 3 hours after exposure but, rather than have the prophylaxis administered by the soldiers themselves, as in the British Army, medical orderlies administered to the American soldiers. However, the US army was not banned from the French

*maisons tolérées* and the infection rates ran out of control to such an extent that in May 1918, an Anglo-American conference on venereal diseases was convened to discuss what measures might be necessary. The war ended before any significant progress was made. On the advice of Albert Neisser, the German Army was adopting similar programs.

## BETWEEN THE WARS IN THE USA

After the First World War there was a marked decline of interest in venereal diseases and, in the USA, federal control programs virtually ceased. While there was an alteration in the sexual mores of people, and sex before marriage was becoming more frequent, nevertheless the matter of venereal diseases was simply not discussed. Because of this, a determined young doctor, Thomas Parran (1892–1968) began to agitate. In 1926, he was appointed Chief of the Venereal Disease Division of the US Public Health Service and, despite the fact that funding became even more limited during the Great Depression, he nevertheless persisted in bringing the problem to national attention. He used the media, against considerable opposition, to do this and his book, *Shadow on the Land: Syphilis* was published in 1937 as a very considerable best seller.<sup>59</sup> He advocated mandatory syphilis serology before marriage and during pregnancy and by the mid 1930s this was largely established. Since he was an epidemiologist, his method of controlling syphilis was based on the case finding by the free provision of serology, prompt treatment and the tracing and examining of contacts. Eventually, in 1938, the National Venereal Disease Control Act was passed which authorized federal funding for a comprehensive control program.

## THE SECOND WORLD WAR AND AFTERMATH

Predictably, during the Second World War, the incidence of venereal diseases rose dramatically again. The role of prostitutes was not so great. Rather, sex did not always have to be paid for as a result of the changing mores of the time. The Japanese, on the other hand, forced women into prostitution as "comfort women", many of whom acquired STIs and both the Russians and the Japanese raped the conquered on a massive scale. The war was fought on a world-wide basis and some servicemen were seeking sex in parts of the world where the tropical venereal diseases were prevalent. In North Africa and in Italy, the problem became so great that the British and American allies decided to use the scarce supplies of penicillin rather than reserving its use for battle casualties alone, and the effect was dramatic. The Nazis regressed and began to include natural healing processes such as the use of leeches, bleeding and dietary measures.<sup>60</sup> In the post-war period with the arrival of penicillin and other antibiotics, it seemed as if it would be simple to control the venereal diseases. Indeed, the incidence of these infections declined markedly and they were perceived to be of much less public health importance than previously. As a result, particularly in America, a reduction in federal funding occurred and even great syphilologists, such as

Earle Moore, turned over his department to the study of chronic diseases at the Johns Hopkins Hospital in Baltimore.

In the United Kingdom, Ambrose King fought strenuously to maintain the nationwide system of clinics<sup>61</sup> and, fortunately, he was successful. Meanwhile, by the 1960s the incidence of STIs was increasing around the world and, particularly in the industrialized world the advent of the oral contraceptive pill, the abandonment of barrier contraception and alteration in the sexual mores mitigated for an expansion of the epidemic. More enlightened legislation changed attitudes to homosexuality and some male homosexuals adopted a lifestyle where anonymous sex with multiple partners, often unprotected, became the norm. This seemed safe enough to them as the bacterial infections, at least, could be easily cured. It all went horribly wrong in the late 1970s and early 1980s when HIV entered this community and spread rapidly. But it was not recognized at that stage that the infection was already well-established in sub-Saharan Africa and it spread with great velocity throughout the continent. Governments often ignored or even denied the situation and the HIV/AIDS epidemic is a human and economic disaster of monumental proportions. The World Health Organization (WHO) estimated, however, that the biggest epidemic would probably occur in the Indian subcontinent because of its social framework and vast population, and the government there was also slow to act. This has not yet been borne out. Infection rates are rising in China, the most populous nation on earth, and it is to be hoped that control measures may limit the spread in that country.

## THE WORLD HEALTH ORGANIZATION

The creation of WHO after the Second World War, with its division of STIs, has been a most beneficial development. It estimates the extent of the problem in countries and regions around the world and it provides technical assistance and training. It is recognized that in resource poor countries the luxury of a doctor-led case finding method of managing these infections is not the most practical approach. The notion of syndromic management has therefore been developed and algorithms of care, appropriate to a particular region, have been made available. This has been most useful in areas of high endemicity but the approach has often met with resistance from the local medical community. The WHO has developed management guidelines for syndromic approach and the antibiotics selected will be based on the known antibiotic resistance pattern (particularly for gonorrhea), in any area. Through its Gonococcal Resistance and Antimicrobial Susceptibility Project (GRASP) networks, it is able to monitor developments.

## Diagnostic Methods

For the most part of the last century, diagnosis of STIs has been made on clinical grounds, on the use of microscopy and culture (with antibiotic sensitivity testing) and on some serological testing (syphilis and HIV). The advent of nucleic acid amplification tests (NAATs) has changed that and some infections (*Chlamydia spp*) now are diagnosed predominantly using NAATs. It is possible to

multiplex these tests to identify more than one organism—tests for identification of *N. gonorrhoeae* and *C. trachomatis* are in widespread use already and soon multiplex tests for organisms causing syndromes such as urethral and vaginal discharge and genital ulceration will be available, identifying newly recognized organisms such as *Mycoplasma genitalium* as well. Recently, in Sweden, a NAAT test failed to identify *C. trachomatis* because the test target, the cryptic plasmid, had developed a 377 bp deletion in some cases, so constant vigilance is essential.<sup>62</sup> In London also, a NAAT test failed to diagnose infection with *C. trachomatis* because an organism had mutated to be plasmid-free, so, again, the target was not available. Rapid Point of Care Tests (POCTs) are being developed now, primarily for use in resource-poor parts of the world, although they will probably be used in the industrialized world as well (the plasmid-free organism<sup>63</sup> was suspected when a new POCT test was being compared with an established NAAT test and the former identified the infection and the latter did not). This is already happening with HIV testing, and to a lesser extent in the identification of syphilis, but availability of these tests and NAATs will enable nonspecialists to more easily make an accurate diagnosis.

## Vaccination

Prevention is always better than cure and, certainly through vaccination, some dangerous diseases have been eradicated (smallpox) and others massively reduced in incidence (polio, diphtheria, and childhood exanthemata). There has always been an aspiration to prevent STIs through vaccination but, until recently, this has been a vain hope. The big prize, of course, would be a vaccine against HIV with, currently, around an estimated 3 million deaths annually from HIV and AIDS and, by 2030, it is estimated that HIV will be one of the major causes of death worldwide, alongside heart disease and stroke. The problem is that ancestral viruses have been in existence for millennia and have learnt how to evade host immune responses. Add to that the extraordinarily rapid rate of mutation during replication and it is understandable that, so far, it has not been possible to produce an effective vaccine. There have been three large efficacy studies, all of which have failed to show any benefit. With the recognition that it will be some time, if ever, that a vaccine will be developed that produces a strong, effective neutralizing antibody response, researchers are looking at ways now to elicit effective T-cell responses against HIV. There may be much to learn from the long-term nonprogressor group, mucosal vaccines are being considered and there is on-going work in macaques to determine whether the protective potential of alloimmunity can be incorporated into effective vaccines against the simian immunodeficiency virus (SIV).<sup>64</sup>

Effective vaccines against hepatitis A and B have been available for some years, initial studies on new preventative and prophylactic herpes vaccines were unsuccessful in the 1990s, but there is hope that progress is being made and that successful vaccines may be in the pipeline. However, the one recent success has been the development and licensing of bivalent and quadrivalent HPV

vaccines. Industrialized countries are beginning to give these to early teenage girls to prevent the development of oncogenic HPV-driven cervical neoplasia.<sup>65</sup> This strategy is expected to be cost effective and, if it could be rolled out to resource-poor settings, might stop the untimely death of approximately 240,000 women from cervical cancer every year.<sup>66</sup>

## Conclusion

The terms STIs/venereal diseases have been used synonymously throughout this chapter and they have a fascinating history. Their incidence has waxed and waned down the centuries. New infections have been recognized, such as HIV infection, and while its incidence is still rising dramatically all over the world, huge scientific advances have taken place and are of advantage to medicine as a whole. The sexual mores of the world have changed dramatically over the past 100 years, many of the infections are now curable, new methods of diagnosis are available and the level of knowledge of the public has never been greater. Yet mankind has, apparently, not learnt much from all that has gone before and the prevalence of these infections is being maintained at a high level and is even rising. The war between disease and doctors, fought on the battleground of the flesh, may have a beginning, a middle but no end. Infections and epidemics arise within society and will remain a social product no less than the medicine, which opposes it. Civilization brings not just discontents but diseases too.<sup>67</sup>

### Introduction

Sexually transmitted infections (STIs) represent a major public health problem. STIs are the cause of acute illness, long-term disability and death in women, men and infants, with tremendous economic consequences at individual and community level.

STIs were previously known as venereal diseases. Due to the stigma attached to this group of diseases, in the 70s the name was changed to sexually transmitted diseases. Recently, it has been discussed that 'disease' is not the most appropriate term to describe infections that may remain asymptomatic for many years or would never develop symptoms. Therefore, the World Health Organization (WHO) has recommended instead the use of sexually transmitted infections for the group of infectious diseases transmitted by sexual activity ([www.WHO.int](http://www.WHO.int)).<sup>1</sup>

In spite of available effective treatment for bacterial STIs, the incidence of STIs continues to escalate worldwide. WHO estimates that 480 million new cases of selected but curable STIs (Chlamydia, gonorrhea, syphilis, and trichomoniasis) occurred worldwide in 2005 (Fig. 3.1).<sup>2</sup>

Table 3.1 shows the breakdown of these infections according to WHO regions. WHO estimates are based on results from published and unpublished studies on prevalence of STIs and

**Fig. 3.1:** Estimated new cases of curable STIs among adults (WHO 2005).<sup>2</sup>

surveillance data. Data from different studies vary greatly in quality and accuracy and therefore the estimations should be taken with caution. Although aggregate data at national level may hide microepidemics in certain groups or geographic areas, the data are useful to analyze trends at national level.

**Table 3.1:** Estimated Incidence of Curable STIs by Region, (WHO 2005)<sup>2</sup>

WHO region	Chlamydia	<i>Neisseria gonorrhoeae</i>	Syphilis	<i>Trichomonas vaginalis</i>	Total
African region	10.0	17.5	3.4	78.8	109.70
Region of the Americas	22.4	9.5	2.4	54.9	89.20
Eastern Mediterranean region	5.7	6.5	0.6	12.60	25.40
European region	15.2	4.6	0.3	24.50	44.60
South-East Asia region	6.6	22.7	2.9	38.60	70.80
Western Pacific region	41.6	26.9	1.0	39.10	108.70
Global Total	101.5	87.7	10.6	248.5	448.40

\*This chapter is based on a WHO document "Prevalence and Incidence of Selected Sexually Transmitted Infections: *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, syphilis, and *Trichomonas vaginalis*: methods and results used by WHO to generate 2005 estimates" (WHO 2011, in press) developed by George Schmid and Julia Samuelson (WHO Staff members) and Jane Rowley (Independent consultant).

The burden of STIs is not only due to the acute episode of the infections, but it is determined also by the long-term and severe sequelae that many STIs may cause, such as infertility, ectopic pregnancy, and pelvic inflammatory disease.<sup>3</sup> It has been shown that both ulcerative and nonulcerative STIs enhance the transmission of human immunodeficiency virus.<sup>4</sup> In community trials conducted in Tanzania, the improvement in the management of STIs resulted in the reduction of the incidence of HIV by about 40%.<sup>5</sup>

Available data on prevalence and incidence of STIs is limited since STIs are usually not statutory notifiable. In many countries, therefore, the only data existing are from cross-sectional or point prevalence studies conducted among selected population. Many STIs are asymptomatic, or people are reluctant to seek healthcare due to the stigma attached to STIs. Consequently, in countries with STIs surveillance systems, the available data tend to underestimate actual prevalence and incidence rates.

Prevalence studies carried out in selected populations are not necessarily representative of the entire population. Pregnant women represent women of reproductive age who are fertile and seek prenatal care, but exclude single women, those who may have become subfertile or infertile due to a previous STI, and those with limited or without access to antenatal care services.

Accurate STIs prevalence data are needed in the planning, management, and evaluation of a control program. The importance of STIs as a public health problem needs to be estimated in order to advocate for sufficient resources allocation for their control and to assist decision-makers in defining and setting health priorities. Assessment of the magnitude of the problem posed by STIs should include a description of the incidence and prevalence of the diseases, characteristics of the affected population and any possible complications. Therefore, it is necessary to have a comprehensive and reliable surveillance system in order to know the distribution of STIs in the different age groups, sex, and geographical areas. A reliable system would enable follow-up of trends of STIs prevalence in the population.

## Surveillance of Sexually Transmitted Infections

Public health surveillance has been defined as: *the ongoing systematic collection, analysis, and interpretation of health data essential for planning, implementing, and evaluating public health activities.* Surveillance needs to be linked to timely dissemination of the data, so that effective action can be taken to prevent disease.<sup>6</sup>

The objectives of surveillance are to:

- monitor trends in diseases,
- identify problems that need intervention,
- improve effectiveness of prevention or healthcare resources,
- evaluate the impact of specific interventions.

According to the World Health Organization,<sup>7</sup> specific objectives of STIs surveillance are to:

- estimate the magnitude of the problem of STIs and improve program management;

- inform treatment recommendations and improve patient care.

There are four components of STIs surveillance needed in order to achieve effective control programs. These components are:

1. Case reporting.
2. Prevalence assessments.
3. Assessment of STI syndrome etiologies.
4. Antimicrobial resistance monitoring.

**Case reporting:** The report of cases of STIs by healthcare providers to public health authorities. Cases can be reported using an etiologic or syndromic diagnosis. Etiologic reporting is based on laboratory diagnosis, and therefore requires a well-developed laboratory system. Syndromic diagnosis may be used when access to laboratory services is limited. However, the specificity of this approach is lower than that of the etiologic diagnosis.<sup>8</sup> Case reporting can be conducted on a universal or sentinel basis depending on the national reporting system as well as on how services for the prevention and control of STIs are organized and delivered. Universal case reporting is the process where all healthcare facilities tally and report every case seen. Sentinel site case reporting is the collection of data from a select number of sites to capture health problems among “sentinel” populations thought to be representative of a population group of interest.

**Prevalence assessments and monitoring:** To regularly estimate prevalence of at least one STI and by doing so, monitor trends over time. Prevalence surveys are cross-sectional surveys that establish the frequency of disease and other factors in a community. They are useful to estimate the number of people in a population who have STIs and can also identify the differences in the frequency of infection in different population groups.

**Assessment of STI syndrome etiologies:** An important component of STI surveillance in countries with limited laboratory services. Periodic surveys provide information to keep guidelines for treatment of STIs updated.

**Antimicrobial resistance monitoring:** Due to the increasing rate of resistance of *Neisseria gonorrhoeae*, it is important to monitor antibiotic resistance in order to obtain current information for updating of treatment guidelines and to detect newly emerging resistance.

Surveillance systems should be evaluated periodically, *to promote the best use of public health resources by ensuring that problems of public health importance are under surveillance, that surveillance systems operate efficiently, and the information provided by surveillance systems is useful for public health practice. The evaluation should include recommendations for improving quality and efficiency.*<sup>9</sup>

It is very important to understand the magnitude of the problem posed by STIs in order to plan appropriate prevention campaigns, targeting key populations at higher risk of STIs. Studies evaluating the sensitivity of STIs surveillance systems are limited. In the Netherlands, the sensitivity of the statutory notification for gonorrhea has been estimated to be as low as 30%.<sup>10</sup>

Cultural values, myths, and beliefs are attached to sexual relations and therefore also attached to the infections. STIs are not merely a medical problem but a complex sociocultural and political problem. Cultural values and myths related with sexual issues contribute to the stigmatization of infections transmitted by sexual intercourse. Therefore, in order to achieve a sustainable reduction in the prevalence of STIs, a multidisciplinary approach is needed.

Effective treatment is an important component in the management of STIs, but alone it is not enough unless it coexists with public education and counseling. Strengthening of health services including laboratory facilities and mechanism for storage and distribution of drugs for treatment are essential steps in the management and control of STIs.

### Dynamics of the Transmission of STIs

The potential of an infectious disease to spread in a population or the rate of spread of one given disease is determined by:

**Contact pattern:** The rate of exposure of susceptible persons to infected individuals.

**Transmission probability:** The efficiency of transmission or the probability that a contact between an infected person and a susceptible one results in successful transmission of the pathogen so that the susceptible person becomes infected. The transmission probability depends on factors associated with the infected person, the susceptible contact, and the pathogen.

**Infectiousness:** The length of time an infected persons remains infectious, i.e., the period within the contact between an infected person and a susceptible one may result in the spread of the infection.

**Population immunity:** The proportion of individuals those are immune to the disease due to previous exposition to the pathogen or due to vaccination.

The rate of spread of STIs can be calculated using the reproductive rate of infection or average number of secondary cases of STIs resulting from a new case. The following model represents the reproductive rate of infection:  $R_0 = \beta \times c \times D$

In this model, ' $\beta$ ' represents the mean probability of transmission per exposure, ' $c$ ' is the mean rate of sexual partner change within the population, and ' $D$ ' is the mean duration of infectiousness of the newly infected persons.<sup>11</sup> If  $R_0$  remains less than 1, the infection eventually disappears from the population.

The transmission probability per partnership for *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Treponema pallidum* is estimated to be 0.5, 0.2, and 0.6 respectively<sup>12</sup> and the mean durations of infectiousness are presented in Tables 3.2 and 3.3.

The model used for the calculation of the rate of spread is a mathematical model that may contribute to the understanding of the 'dynamics of STIs.' However, the occurrence of STIs and their persistence in the population depend upon many complex factors related to both the individual and the community.

**Table 3.2:** Average Duration of Infection for Chlamydia and *Neisseria gonorrhoeae*<sup>2</sup>

Infection	Asymptomatic and not treated		Symptomatic and treated	
	Male	Female	Male	Female
<i>Chlamydia</i>	1.25 years	1.25 years	4 weeks	8 weeks
<i>Neisseria gonorrhoeae</i>	5 months	6 months	2 weeks	4 weeks

**Table 3.3:** Average Duration of Infection for Individuals with Syphilis Depending on Stage in which They are Treated<sup>2</sup>

Primary	1 month
Secondary	3 months
Latent	3 years
Tertiary	15 years

Heterogeneity in contact rate, transmission probability, and duration of infectiousness produces different reproductive rates of the infection in different subgroups (Fig. 3.2).

The sexual contact pattern in a population is not a random mixing. Among people with high rate of concurrent sexual relationship the rate will be high, and therefore they may contribute to the persistence of infections through sexual route. Interaction within the subpopulation with high sexual activity, or core group, and the pattern of sexual contact between this group and the rest of the population is an important determinant of the spread of infection.

There are some characteristics of STIs that may contribute to the poor awareness of STIs in the population and consequently may slow down the progress of control programs:

- A high percentage of persons with STIs never present with symptoms and therefore, they are not aware of being infected or infectious. The decreased likelihood of seeking treatment results in higher percentage of undetected and untreated infections with risk for spreading and for complications.
- Complications after infection may develop many years after the acute episode. Due to the time lag between the acute episode of the infection and the development of sequelae, those at risk will not easily understand the relationship and consequently the need of behavioral change.
- Causative organisms change genetically, and therefore the development of effective treatments (drugs and vaccine) may be difficult.

**Fig. 3.2:** Dynamics of the STIs epidemic in the population.

- Microorganisms develop resistance against antibiotics, which contribute to treatment failure and prolongation of period of infectiousness.
- Due to the stigma attached to STIs, people are reluctant to seek care. In addition, health staff is not always prepared to talk about sexual issues with patients seeking care and therefore, the opportunity of tracing contacts may be missed. Both factors contribute to the persistence of infected people in the population.
- Many STIs induce limited or no acquired immunity, therefore individuals remain susceptible to reinfection.
- Lifelong persistence of virus such as HIV and herpes simplex virus contributes to life long infectiousness.

## Dynamics of the STIs Epidemic

There are many biological, cultural, and socioeconomic factors that contribute to the acquisition of an STI and hence to the perpetuation of the epidemic. Wasserheit<sup>13</sup> divides the underlying factors that contribute to the perpetuation of the epidemic into:

- (a) factors related to the microenvironment, i.e., those directly related to the individual;
- (b) factors related to the macroenvironment.

These two levels are closely related to each other: microenvironment could modify and be modified by macroenvironment (Table 3.4).

### MICROENVIRONMENTAL FACTORS

**Gender and age:** Cervical ectopy, which is frequently found in younger females, has been found to be a risk factor for acquisition of STIs. This is a factor that contributes to the increased vulnerability of younger women to STIs.<sup>14</sup>

**Age at first coitus:** Women with early sexual debut (10–14 year-old) have an increased risk of contracting STIs due to

immaturity of their reproductive tract and due to the increased number of years they will be exposed to STIs in comparison with those women who have their first sexual intercourse at adult age.<sup>15</sup>

**Anal sex:** Anal sex has been reported to be associated with self reported history of genital warts, genital herpes, and gonorrhea.<sup>16</sup>

**Sex during menstruation:** Tanfer et al.<sup>17</sup> found a strong association between sexual intercourse during menstruation and history of self reported STIs.

**Male circumcision:** Diseker and colleagues<sup>18</sup> have shown that the risk of contracting gonorrhea and syphilis is higher among uncircumcised men than among circumcised ones. No differences were found for chlamydia. A randomized controlled intervention trial conducted in a general population of South Africa has showed that male circumcision is associated with a protection of 60% (95% CI: 32–76%).<sup>19</sup> Trauma that the foreskin in uncircumcised men is exposed to during sexual intercourse, inflammation underneath the foreskin, and the high density of langerhans cells which are target cells for HIV are factors that may contribute to the increased risk for HIV in the uncircumcised.<sup>20</sup>

**Drugs and alcohol:** It has been suggested that alcohol consumption in conjunction with sexual activity may be related with impaired ability to practice safe sex.<sup>21,22</sup> Caetano et al.<sup>23</sup> found that people who had five or more drinks at one sitting have multiple sexual partners more frequently.

Epidemiological studies of the epidemic of syphilis in USA in the 1980s identified exposition to cocaine as a risk factor.<sup>24</sup> The use of cocaine may contribute to a decrease of inhibitions and an increase in sexuality. Men who have sex with men who use alcohol and drugs are at especially high risk for sexually transmitted infections.<sup>25</sup> It is not uncommon that drug users exchange sex for drugs and therefore they may have a higher number of sexual partners.<sup>26</sup>

### MACROENVIRONMENTAL FACTORS

**Poverty:** It may negatively influence the STIs epidemic by limiting the access to healthcare services leading to a delay in early diagnosis and treatment, or by limiting the access to education, which may decrease the accessibility to health information. In addition, poverty may result in increase in both male and female sex trade.

**Gender inequality:** In many countries, women are in a dependent situation, and therefore not able to negotiate issues related to their own sexual life including the use of condom.<sup>27</sup>

**Lack of openness to discuss sexual issues:** In many countries due to cultural or religious barriers, youngsters do not receive adequate information on sexual issues from adults but usually the only source of information are their peers. The information that the youngsters receive from their peers may be incomplete

**Table 3.4:** Determinants of STIs Epidemic

Microenvironment	Macroenvironment
<ul style="list-style-type: none"> <li>● Biological               <ul style="list-style-type: none"> <li>□ Gender</li> <li>□ Age</li> <li>□ Coexistence of other STIs</li> <li>□ Pregnancy</li> </ul> </li> <li>● Immunological</li> <li>● Behavioral               <ul style="list-style-type: none"> <li>□ Age at coital debut</li> <li>□ Multiple sexual partners</li> <li>□ Sexual practices:                   <ul style="list-style-type: none"> <li>— Anal sex</li> <li>— Sex during menstruation</li> </ul> </li> <li>□ Male circumcision</li> <li>□ Drug or alcohol use</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>● Cultural, social, and economic               <ul style="list-style-type: none"> <li>□ Poverty</li> <li>□ Gender inequality</li> <li>□ Health seeking behaviors</li> <li>□ Silent on sex issues</li> <li>□ Stigma and discrimination</li> </ul> </li> <li>● Epidemiological               <ul style="list-style-type: none"> <li>□ STIs prevalence</li> </ul> </li> <li>● Demographic               <ul style="list-style-type: none"> <li>□ Population age structure</li> <li>□ Sex ratio</li> </ul> </li> <li>● Political and structural</li> </ul>

or inaccurate and therefore it may not contribute towards safer sexual behavior.

**Stigma and discrimination:** Reaching key populations at higher risk of STIs particularly sex workers and men who have sex with men for services remains a challenge. Stigmatization and discriminations, especially in medical facilities, combined with restrictive laws are frequent obstacles to deliver STI prevention, treatment, and care services in these populations.

**Demographic factors:** In many developing countries, a high birth rate and short life expectancy determine a broad base pyramidal age structure, with a high percentage of the population within the reproductive age and therefore in the 'at risk' groups for STIs.

**Political and structural:** Lack of prioritization regarding STI program that is usually due to different competing public health issues that leads to a discrepancy between STI burden and resources allocated for the program.

## Chlamydia

*Chlamydia trachomatis* is the most common bacterial STIs in Western countries and an increasing public health problem in many developing countries. WHO estimates that 101.5 million new cases of chlamydia occurred worldwide in 2005 among those aged 15–49 years (Fig. 3.3).<sup>2</sup>

The information from developing countries is very scarce, partially due to the lack of cheap and reliable tests, which may hinder laboratory confirmation of suspected cases. Development of laboratory methods for detection of chlamydia infections

such as polymerase chain reaction (PCR), which do not require invasive procedures to obtain test samples, has facilitated both the diagnosis and screening activities in many countries. However, these tests are still very expensive and therefore of limited access in countries having inadequate resources. It is estimated that 85% of women and 40% of men are asymptomatic and therefore only detectable with screening programs.<sup>28</sup>

Chlamydia infections, if untreated, may persist for years. It is believed that spontaneous remissions may occur, but the rate for such remissions is not known. Studies on women with untreated chlamydia infections have shown culture positivity for more than 60 days; other studies have reported that infection may persist for years. In a review of the literature, Golden and colleagues<sup>29</sup> concluded that current data do not allow a reliable estimation of the duration of genital infection. It is uncertain whether immunity develops after exposure to chlamydia.

Chlamydia is less easily transmitted than gonorrhea.<sup>30</sup> In a study among patients with STIs and their sexual partners, a deterministic model was developed to calculate transmission possibilities.<sup>31</sup> It was estimated that transmission from men to women was 0.40 while for women to men it was 0.30. The study did not quantify the frequency of sexual intercourse and therefore the risk for transmission during a single sexual intercourse may be lower than observed in the study (Table 3.5).<sup>2</sup>

Stergachis and colleagues<sup>32</sup> found that some of the risk factors for acquisition of chlamydia among women are: age below 24-year-old, being single, having more than 2 sexual partners and practice of vaginal douching. Franceschi and colleagues investigated the prevalence of chlamydia on four continents and

found that the chlamydia prevalence was greater in women aged 15–24 years than among those 25–44 years.<sup>33</sup>

Chlamydia infection during pregnancy may cause conjunctivitis or severe respiratory infections in the newborn. In a study conducted in Papua New Guinea it was shown that 57% of the conjunctivitis and 33% of cases of severe pneumonia in children under 3 months were due to *Chlamydia trachomatis*.<sup>34</sup>

Studies conducted among pregnant women have shown prevalence rates from 3% in Ghana to 29% in Fiji as shown in Table 3.6.<sup>35–43</sup>

Studies conducted among selected populations have shown prevalence of 41% among commercial sex workers in Indonesia (2000),<sup>44</sup> 32% in China (2001),<sup>45</sup> 25% in Bangladesh (2000),<sup>46</sup> and 5.8% in Canada (2001).<sup>47</sup> Prevalence of chlamydia among students and in the general population according to some studies are shown in Table 3.7.<sup>48–56</sup>

## Gonorrhea

Gonorrhea is caused by *Neisseria gonorrhoeae* and transmitted almost exclusively by sexual contact or perinatally. The importance of gonorrhea is not only due to the acute symptoms that the infection causes but mainly due to the risk of complications and sequelae. If untreated, genital gonorrhea may lead to pelvic inflammatory disease in about 10–20% of women, a complication that may result in tubal occlusion and infertility. In men, untreated infections may result in epididymitis, prostatitis, and infertility.

Genital gonorrhea may be asymptomatic in both men and women, but it is more frequently silent in women: 30–80% of female cases of gonorrhea are asymptomatic in comparison with less than 5% of infected men.<sup>57</sup>

The risk of transmission of gonorrhea from an infected woman to her male partner has been estimated to be about 20% for a single intercourse, with a significant higher risk, about 60–80%, with more than four intercourses.<sup>58</sup>

The WHO estimates that gonorrhea accounted for 20% of the new cases of curable STIs worldwide in 2005, with 88 million new cases among adults aged 15–49 years (Fig. 3.4, Table 3.8).<sup>2</sup>

Between 1991 and 1996, a decline in number of gonorrhea cases was observed in many western European countries.<sup>59</sup> However, in early 2000 an increased incidence of gonorrhea has been reported in European countries.<sup>60,61</sup>

Gonorrhea is a common cause of urethral discharge, and it was found to be responsible for 69% of cases among men consulting due to urethral discharge in a clinic in the Central African Republic.<sup>62</sup> Prevalence rates in asymptomatic women in suburban community in Sudan were 1.2%.<sup>63</sup> Reported prevalence

for adult male population was 0% in Japan,<sup>64</sup> 0.4% in India,<sup>65</sup> and 1% in Tanzania.<sup>66</sup>

Results of *Neisseria gonorrhoeae* prevalence studies conducted among pregnant women are presented in Table 3.9.<sup>35,37–39,42,43,67,68–72</sup>

## Syphilis

The prevalence of syphilis declined worldwide after the introduction of penicillin in the 1950s. In many Western countries, this trend was followed by an increase in the 1960s and 1970s probably due to the sexual liberation that took place during that period.

During the last decade, the prevalence of syphilis has decreased in many countries.<sup>73–76</sup> However, syphilis infection still is an

**Fig. 3.4:** Estimated new cases of genital gonorrhea among adults (WHO 2005).<sup>2</sup>

important public health problem in many developing countries and a cause of increased concern in many countries in Eastern Europe and Asia.<sup>77–80</sup> In the newly independent states of the former Soviet Union, the rates of syphilis showed an increase of prevalence rates from 5.15/100,000 in 1990 to 120–170 per 100,000 in 1996.<sup>81</sup> A decrease or stabilization in same locations has been observed since 1997.<sup>82</sup>

WHO estimates that 10.6 million new cases of syphilis occurred worldwide in 2005 (Fig. 3.5 and Table 3.10).<sup>2</sup>

The risk of transmission from men to women is calculated to be less than 30%.<sup>83</sup> It has been well-documented that syphilis infection increases the risk of HIV transmission by at least 3-fold.<sup>84</sup> In addition, there is some evidence to suggest that syphilis infection may increase the HIV viral load of

**Fig. 3.5:** Estimated new cases of syphilis among adults (WHO 2005).<sup>2</sup>

coinfected patients, and may increase the risk of mother-to-child transmission of HIV.<sup>85</sup>

In seroprevalence studies among African pregnant women prevalence rates have been found to be as low as 0% in Democratic Republic of Congo and up to 6.8% in Zambia as shown in Table 3.11.<sup>43,67,86–89</sup>

Population-based syphilis seroprevalence studies in rural area in Gambia showed rate of 2.3% in women,<sup>90</sup> DHS National Survey in Uganda showed 3.1% syphilis seroprevalence in men and 3.1% in women,<sup>91</sup> and 6.5% in women and 7.7% in men in Zambia.<sup>92</sup> Community-based survey in Madagascar showed prevalence of 11.8% in male population.<sup>93</sup>

Among patients with genital ulcer disease, syphilis was found to be responsible for 29% of cases in Madagascar,<sup>94</sup> 19% in Rwanda,<sup>95</sup> 12% in Uganda,<sup>96</sup> 10% in India,<sup>97</sup> and 3.4% in Singapore.<sup>98</sup>

## Chancroid

Chancroid, caused by *Haemophilus ducreyi*, is a common cause of genital ulcer in developing countries, particularly in sub-Saharan Africa. However, due to the absence of a cheap and reliable test, prevalence studies from resource poor countries are limited. The accuracy of clinical diagnosis may range from 33% to 80%, and it is related to the prevalence of chancroid in the population and the experience of the physician.<sup>99</sup> The sensitivity of culture may vary depending upon the culture media used and it is only about 75% at best.<sup>100</sup> Another diagnostic method that may be used is serological tests, with a sensitivity of 60–80% compared with culture. Serological tests, however, do not allow for differentiation between a recent and a past infection.<sup>101</sup> Newer methods as polymerase chain reaction (PCR) have a sensitivity of 95% but are expensive and require good laboratory set up.

Few cases were reported in USA between 1950 and 1980. An increasing number of cases were reported during the 1980s, peaking in 1987.<sup>102</sup> Since then, the prevalence of chancroid has decreased. However, outbreaks have been reported.<sup>103</sup> In a study of STD patients with ulcer from 10 cities, *H. ducreyi* was detected in ulcer specimens from patients from only 2 cities.<sup>104</sup>

Prevalence studies in Ethiopia showed a prevalence of 10% among pregnant women and 19.4% among women attending gynecological, obstetric, and family planning clinics.<sup>105</sup>

In a seroprevalence study conducted among rural population in Uganda, 1000 individuals between 15 and 54 years were tested within 2 years interval. The prevalence found was 9.8% for men and 7.3% for women, with an incidence rate per 1000 person years of 24.6 and 20.0 for men and women respectively.<sup>106</sup> Higher seroprevalence rates were found among selected population with 86% positive for IgG and 69% for IgA among commercial sex workers in Lagos, Nigeria,<sup>107</sup> 68% in migrant mine worker in South Africa,<sup>108</sup> and 26.5% in truck drivers in Kenya.<sup>109</sup>

In studies aimed to determine the etiology of genital ulcer disease, chancroid was found to be a relatively common cause.

**Table 3.11:** Syphilis Prevalence Rates Among Pregnant Women in Africa<sup>43,67,86–89</sup>

Country	Prevalence	Studied population	Reference
Democratic Republic of Congo	0	Pregnant women attending ANC clinic	Kinoshita-Moleka R et al., 2008 <sup>67</sup>
Mozambique	4.7	Pregnant women attending ANC clinic	Lujan et al., 2008 <sup>43</sup>
Nigeria	1.87	Pregnant women attending ANC clinic for first visit	Federal Ministry of Health, Nigeria: 2005 National HIV/Syphilis seroprevalence sentinel survey among pregnant women attending ANC clinics, April 2006 <sup>86</sup>
Tanzania	1.6	Women attending 1 of 6 ANC clinics, 15–49 years	Yahya-Malima et al., 2008 <sup>87</sup>
Uganda	1.6	Pregnant women attending booking visit at Entebbe district hospital, 15–40 years	Tann CJ et al., 2006 <sup>88</sup>
Zambia	6.8	Pregnant women attending ANC clinic, 14–44 years	Zambia antenatal clinic sentinel surveillance report: 1994–2004 (2005) <sup>89</sup>

Almost 52% of cases with genital ulcer in Bombay, India,<sup>110</sup> 26% of cases in Malawi,<sup>111</sup> 33% of cases of genital ulcer in Madagascar,<sup>94</sup> 23.7% in Jamaica,<sup>112</sup> and 23% in Pune, India were labelled to be due to chancroid.<sup>97</sup> Cases in the first two studies were culture positive and the remaining studies used PCR for diagnosis of chancroid.

O'Farrell et al.<sup>113,114</sup> found that in Durban, South Africa, 22% of the ulcers in men and 14% in women were due to *H. ducreyi*, while a more recent study found positive culture for *H. ducreyi* in 38.1% of cases with genital ulcer.<sup>100</sup>

## Lymphogranuloma Venereum

Caused by *Chlamydia trachomatis* (serovar L1, L2, and L3), lymphogranuloma venereum (LGV) is still endemic in parts of Africa, India, and Southeast Asia. The infection is more common in women than in men, probably due to asymptomatic and undiagnosed infections among men rather than a true lower prevalence. In a study among attendees to an urban STD clinic in Nigeria, lymphogranuloma venereum was the most common cause of genital ulcer among women.<sup>115</sup>

In studies to establish the etiology of genital ulcer diseases conducted in different countries, the percentage of ulcer due to lymphogranuloma venereum varied from 24% in Madagascar,<sup>116</sup> 7% in Lesotho,<sup>8</sup> 3.9% in Jamaica,<sup>117</sup> and 1–1.6% in Singapore.<sup>98</sup>

LGV was a rare condition in Western Europe and USA prior to 2003. Since this time different outbreaks of LGV proctitis have been reported in Europe, North America, and Australia among men who have sex with men: 244 cases by December

2005 in France, 232 cases by March 2007 in the Netherlands, 492 cases by April 2007 in UK, and 88 cases by September 2007 in Canada.<sup>118</sup> The majority of the reported cases were HIV infected MSM with higher risk sexual behavior such as unprotected anal sex, fisting, and sharing sex toys.

## Trichomonas

In spite of being one of the most common STIs available, accurate data on the prevalence of trichomoniasis is limited because few countries include this condition in the existing surveillance of STIs. The recent publication showed high prevalence of infection caused by *Trichomonas vaginalis* (TV), in male population.<sup>119,129</sup> According to some researchers the laboratory methods as microscopy and culture that have been mainly used for TV infection diagnosis before molecular methods were established led to some underestimation of infection particularly among men. The currently available newer generation diagnostics (e.g., LCR and PCR) that are more sensitive and specific can be therefore, used in order to determine the level of prevalence of TV infection, both symptomatic and asymptomatic, in male and female population.<sup>120</sup>

The infection with *Trichomonas vaginalis*, usually acquired via sexual contact, may be asymptomatic in up to 80% of the women with laboratory confirmed infections. Trichomonas infection is believed to facilitate the spread of HIV,<sup>121</sup> and infections of pregnant women have been associated with low birth weight infant and preterm delivery.<sup>122</sup>

The WHO estimates that 248.5 million new cases of TV infection occurred worldwide in 2005 (Fig. 3.6 and Table 3.12).<sup>2</sup>

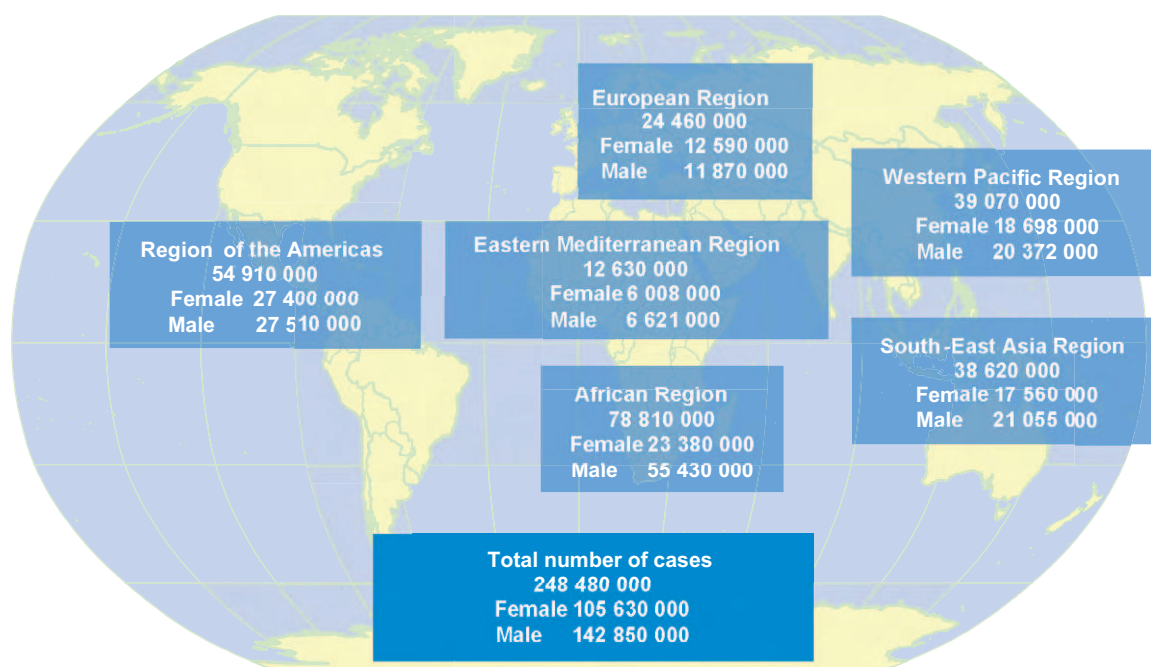

Fig. 3.6: Estimated new cases of trichomoniasis among adults (WHO 2005).<sup>2</sup>

China	3.2	Pregnant women; 1st ANC visit	Chen XS et al., 2006 <sup>37</sup>
Lao	1.8	Pregnant women (<20 weeks) at first visit to Sethiathirath or MCH hospital, population	Thammalangsy S et al., 2006 <sup>42</sup>
Mongolia	6.7	10 randomly selected ANC clinics	Report from MOH Mongolia, 2007 <sup>69</sup>
Samoa	20.8	Pregnant women; out of the women living in villages outside of Apia on the main island of Upolu (28, 68.2%), with the remainder living in Apia (132, 31.4%).	Sullivan EA et al., 2004 <sup>130</sup>

Prevalence studies in rural women showed prevalence rates of 2.8–5.1% in Thailand,<sup>123</sup> 15.1% in Bali,<sup>124</sup> 14–18% in South Africa,<sup>125,126</sup> 22.7% in Dar es Salaam, Tanzania,<sup>127</sup> and 23.8% in Uganda.<sup>128</sup> The prevalence rates of trichomoniasis among pregnant women in various countries are shown in Table 3.13<sup>37,42,69,129,130</sup>

*Trichomonas vaginalis* was found to be the etiological cause in 4.1–24.5% of men with urethral discharge in studies from Benin, Burkina Faso, Cote d'Ivoire, Ghana, Guinea, Mali, Senegal.<sup>131</sup> In Malawi, trichomonas was found in the urethra of 20.8% among symptomatic and 12.2% among asymptomatic men.<sup>132</sup>

## Herpes Simplex Virus

Herpes simplex virus 2 (HSV-2) is responsible for over two-third of all episodes of genital herpes and more than 5% of recurrent cases.<sup>133</sup> The majority of infections are unapparent or not recognized as genital herpes,<sup>134</sup> and consequently, estimation of the prevalence of herpes in the population, based on clinically apparent genital disease underestimates the true prevalence. Genital herpes infections are usually associated with an antibody response and therefore, seroprevalence studies are more accurate as an indicator for prevalence. Between 20% and 30% of young adults are seropositive for HSV-2.<sup>135</sup> HSV-2 seropositivity increases with age and it is correlated with socioeconomic status and number of sexual partners.

In studies conducted among sexual partners with discordant serology for herpes, it has been shown that the risk of contracting infection was about 10% per year, and the risk was higher for women (16.9) than for men (3.8). In women, the risk was lower for those who had HSV-1 antibodies. About 70% of the cases were acquired by sexual contacts that occurred during asymptomatic shedding.<sup>136,137</sup>

Genital herpes infection increases the risk of acquisition of HIV-1,<sup>138</sup> and the risk of spreading HIV infection due to high level of HIV-DNA in herpetic lesions.<sup>139</sup> It has been observed that the frequency of recurrent herpes infection in individuals who are HIV-1 positive is higher than for those who are HIV negative.<sup>140</sup>

Seroprevalence studies conducted among adolescents younger than 20-year-old have shown prevalence rates of 25–30% in Africa, 5–14% in USA, and 1.5% in European countries.<sup>141</sup> In USA, the prevalence of HSV-2 rose by 30% from 16.4% in 1976–1980 to 21.9% in 1988–1999.<sup>142</sup> In a literature review conducted by O'Farrell,<sup>143</sup> it was observed that herpes was one of the leading causes of genital ulceration in many countries and that the prevalence of herpes has increased between 1966 and 1999. In a study conducted among rural adults in Japan, the prevalence of HSV-2 decreased from 10.2% in 1973 to 1.2% in 1993.<sup>144</sup>

The WHO worked with colleagues at Imperial College, London, to model the estimated prevalence and incidence of HSV-2 infections. The total number of people aged 15–49 years who were living with HSV-2 infection worldwide in 2003 is estimated to be 536 million (Table 3.14) while the total number of people who were newly infected with HSV-2 in 2003 is estimated to be 23.6 million.<sup>145</sup>

Herpes virus infection is a common cause of consultation in STD clinics representing 24.6% of the total cases of STDs seen in clinics in Italy,<sup>146</sup> 25% in Spain,<sup>147</sup> 25.7% in New Zealand,<sup>148</sup> 32.3% in the Netherlands,<sup>149</sup> 42.9% in Tanzania,<sup>150</sup> overall prevalence of 55% in Paris with 67.3% and 44% among men and women, respectively,<sup>151</sup> and 64% in female STD attendees aged 18–35 in USA.<sup>152</sup>

\*Adapted from reference.<sup>145</sup>

Genital herpes is a common cause of genital ulcer in Africa. It was detected in 19% of cases with genital ulcer in Rwanda,<sup>95</sup> 42.5% in Nigeria,<sup>115</sup> 49% in Uganda,<sup>96</sup> and 35.8% in South Africa.<sup>153</sup>

Similar studies in Singapore,<sup>98</sup> Jamaica,<sup>112</sup> and Madagascar<sup>94</sup> have showed a high frequency of herpes genital infection among cases with genital ulcer, 71.3%, 52%, and 10%, respectively.

### Human Papillomavirus Infection

There are more than 100 different genetic types of human papillomavirus (HPV) but it is the genotype 6 which is most commonly detected in genital warts. Infections with HPV are often subclinical or asymptomatic and an acute infection may be diagnosed only by the detection of HPV DNA in genital tract. Serological evidence of antibodies is sometimes the only indication of past exposition to the virus. Spontaneous regression of HPV infection was seen in 80% of women from a cohort study in Sweden, with a decline of the prevalence in the cohort from 21% to 8.3% during a 2-years interval.<sup>154</sup>

Seroprevalence in women without sexual experience is low. Prevalence rates increase to reach the highest percentage in sexually active young women to again decrease in older women.<sup>155</sup> However, in a population based study in Mexico for HPV seroprevalence, two peaks were detected, first in women in the age group under 25 years and the second in those aged 65 years and older.<sup>156</sup> In USA, it has been estimated that 1% of sexually active adults have genital warts, and that at least 15% have subclinical infection as detected by HPV-DNA assays.<sup>157</sup>

Figure 3.7 shows HPV prevalence rates obtained in studies conducted among asymptomatic students in Canada,<sup>158</sup> attendees to family planning clinics and private gynecological practices in South Africa,<sup>159</sup> healthy women aged 20- to 29-year-old in Denmark,<sup>160</sup> healthy sexually active women in Croatia<sup>161</sup> and Sweden,<sup>155</sup> attendees to gynecological clinics in Russia<sup>162</sup> and Greece,<sup>163</sup> pregnant women in Tanzania<sup>164</sup> and women aged 18–40 years in USA.<sup>165</sup>

**Fig. 3.7:** Human papilloma virus prevalence studies among female population.

# Global Epidemiology of HIV Infection

Hammad Ali • Joanne Micallef • Basil Donovan

## 4

### Introduction

Human immunodeficiency virus (HIV) infections appear to be zoonoses derived from the chimpanzee (HIV-1)<sup>1,2</sup> and sooty mangabey monkey (HIV-2).<sup>3</sup> Only when these viruses are transferred to other primate species do they cause disease. In the case of HIV-1, the transfer to humans may have occurred as early as the 1930s.<sup>4</sup> The latter half of the 20th century then provided the social and economic conditions for the ensuing HIV pandemic, including:

- increasing urbanization, fostering prostitution,
- unprecedented travel and migration,
- wars,
- the emergence of injecting drug use (IDU),
- contaminated medical and other skin penetration procedures, and
- high rates of other sexually transmitted infections (STIs), particularly in the developing world.<sup>5–7</sup>

### Routes of Transmission

There are three major routes of HIV transmission: sexual, blood borne, and mother-to-child. The most common route of transmission of HIV is through unprotected sexual contact. Although sexual transmission accounts for about 85% of the global HIV burden,<sup>8–9</sup> the probability of infection through sexual contact appears to be lower than that of infection through other routes of transmission.<sup>10</sup> Transmission can occur when sexual secretions of an infected person come into contact with mucous membrane (oral, genital, or anal) of a noninfected person. The rate of transmission in receptive anal intercourse is much higher (1.7% per act) than vaginal intercourse. The female-to-male transmission rate is 0.04% per act and male-to-female transmission rate is 0.08% per act of vaginal intercourse in high-income countries. However, these rates are 4 to 10 times higher in low-income countries.<sup>11</sup> HIV transmission can also take place through oral sex, although the risk of transmission is too low to calculate.<sup>12</sup> Women are more susceptible to HIV infection than men<sup>13</sup> because of their physiology, vaginal ecology, and higher rate

of sexually transmitted infections (STIs).<sup>14–15</sup> HIV transmission through the sexual route is influenced by many factors, including the use of condoms, the presence of other STIs, male circumcision status, and viral load.<sup>8,16</sup>

HIV transmission also occurs parenterally through the transfer of contaminated blood, blood products, tissues, or organs. This route of transmission is important in IDUs, hemophiliacs, recipients of blood transfusions or organs, medical staff (doctors, nursing staff, and laboratory workers) that deal with infected materials, people who get tattoos and body piercings, and people that receive therapeutic injections in both formal and informal healthcare settings.

HIV can be transmitted from an infected mother to her child during pregnancy, during labor, and through breastfeeding. However, mother-to-child transmission (MTCT) can be reduced through improved health procedures (including caesarean section) and antiviral treatments and provision of formula milk.<sup>9,17–20</sup> The HIV epidemic in the heterosexual population can be assessed by routinely monitoring prevalence among pregnant women; this obviously also helps in preventing MTCT.<sup>21</sup> Probability of HIV transmission through various routes of infection has been listed in Box 4.1.

### HIV Surveillance

The ideal surveillance strategy would be to directly measure HIV incidence—the number of new HIV infections occurring each

#### Box 4.1 Ascending Probability of HIV Transmission Through Various Routes of Infection<sup>8,10,16</sup>

1. Blood transfusion
2. Transmission from mother-to-infant with perinatal zidovudine treatment
3. Transmission from mother-to-infant with perinatal zidovudine treatment
4. Needle sharing
5. Needle stick injury
6. Male-to-male sexual transmission
7. Male-to-female sexual transmission
8. Female-to-male sexual transmission

year. However, as this strategy would require massive population screening at regular intervals, no country has ever attempted it. Instead, countries have focused on measuring HIV prevalence and incidence in selected populations, either through repeat surveys or high levels of voluntary testing.<sup>22–24</sup> Different surveillance methods are discussed in detail in Chapter 6.

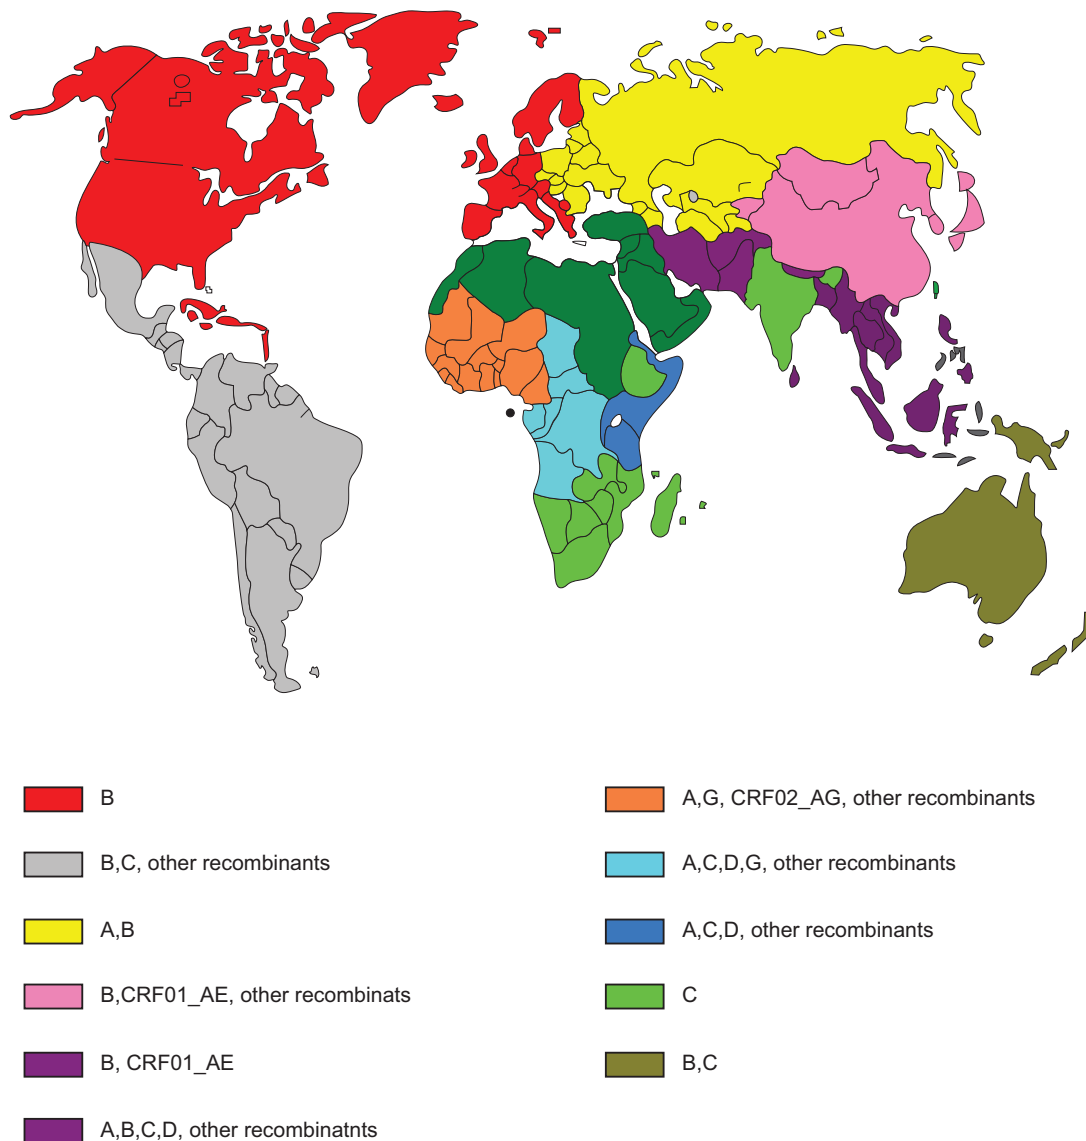

## Genetic Subtypes of HIV

Most HIV infections are caused by the type 1 virus (HIV-1), first identified in 1983.<sup>25–26</sup> HIV-2 was identified 2 years later in patients from Guinea Bissau and other West African countries, and is prevalent in those countries, also in Portugal and parts of India.<sup>27–31</sup> Infrequent cases with HIV-2 have been described in

western countries, such as Spain and France, and in Korea and Philippines.<sup>32–35</sup>

Three groups of HIV-1 (categorized as M, N, and O based on genome differences) have been described. Most infections with HIV-1 are caused by group M viruses that are divided into 9 subtypes (A–D, F–H and K). Subtypes are generally based on variations in RNA sequences that may differ between subtypes by up to 35%.<sup>36</sup> Globally, the prevalence of the different HIV-1 subtypes are diversely distributed (Fig. 4.1).

There are HIV-1 strains with genomes having RNA sequences from different subtypes (recombinants). Recombination occurs when two different HIV-1 subtypes co-infect a single cell and is generally seen in regions where more than 1 subtype is circulating. Recombinant variants that have been characterized

**Fig. 4.1:** Global distribution of HIV-1 subtypes and recombinants within each region in 2004. Subtypes and recombinants with >5% prevalence are shown for each region. Adapted from Hemelaar et al., 2006.<sup>36</sup>

by full genome sequencing and have been identified in at least three epidemiologically unlinked individuals are called circulating recombinant forms (CRFs). CRFs, such as CRF01\_AE and CRF02\_AG, play an important role in epidemics in some regions of the world, such as South and South-East Asia (Fig. 4.1).<sup>36</sup>

An understanding of the genetic characteristics of HIV strains can provide insight into the source of infection for an individual, and can also be applied at a population level to:

- suggest the external geographical origins of HIV isolates,
- determine clustering of subtypes, thus providing insight into the local HIV transmission dynamics,
- indicate the time that has elapsed since a subtype was introduced into a population; based on the assumption that the longer the subtype has been circulating in a population the greater its genetic diversity, and
- identify geographically appropriate vaccine candidates.<sup>37</sup>

The genetic diversity of HIV-1 could result in different biological properties, influencing transmissibility and pathogenicity of subtypes. However, proving this hypothesis has been challenging.<sup>36–37</sup>

## HIV in General Populations

### PREVALENCE ESTIMATION

The overall adult HIV prevalence in any country will generally lie somewhere between the prevalence found in blood donors (people with recognized risk factors are normally excluded from donating blood) and, say, sex workers (typically one of the first

affected populations).<sup>38–40</sup> However, the existence of paid blood donors in some countries can make this population unreliable as a lower limit.<sup>41–42</sup> Women attending antenatal clinics are regarded as providing one of the most reliable and accessible populations in which to measure HIV prevalence in the general sexually active population as they are not attending the service because of illness and because HIV infection does not substantially affect fertility. Nevertheless, a degree of selection bias is inevitable with any surveyed population. The more populations surveyed from a diversity of locations the more reliable the epidemiological picture.<sup>39,41</sup>

### GENERAL POPULATION INDICATORS OF HIV

Since 2000, the global prevalence of adults living with HIV has stabilized at 0.8%.<sup>43</sup> However, the estimated overall number of people living with HIV has increased from 29.5 million in 2001 to 33.4 million in 2008.<sup>43</sup> The increase in people living with HIV is attributed to new infections that continue to occur and the prevention of death due to improved accessibility to antiretroviral treatment.<sup>44</sup> An estimated 2.7 million new HIV infections (2.3 million adults and 0.4 million children below 15 years) and 2 million (1.7 million adults and 0.3 million children below 15 years) deaths occurred in 2008.<sup>43</sup> Analysis of the most recent global HIV prevalence data reveals a disproportionate effect of HIV in sub-Saharan Africa, with 70% of new HIV infections and HIV associated deaths in 2008 occurring within this region (Table 4.1).<sup>43</sup>

**Table 4.1:** Adults and Children Living with HIV, Newly Infected, Adult HIV Prevalence, and Deaths in Adults and Children by Region 2008<sup>43</sup>

	Adults and children living with HIV [range]	Adults and children newly infected with HIV [range]	Adult prevalence (15–49 years) (%) [range]	Adult and child deaths [range]
Sub-Saharan Africa	22.4 million [20.8–24.1 million]	1.9 million [1.6–2.2 million]	5.2 [4.9–5.4]	1.4 million [1.1–1.7 million]
Middle East and North Africa	310,000 [250,000–380,000]	35,000 [24,000–46,000]	0.2 [<0.2–0.3]	20,000 [15,000–25,000]
South and South-East Asia	3.8 million [3.4–4.3 million]	280,000 [240,000–320,000]	0.3 [0.2–0.3]	270,000 [220,000–310,000]
East Asia	850,000 [700,000–1 million]	75,000 [58,000–88,000]	<0.1 [<0.1]	59,000 [46,000–71,000]
Latin America	2.0 million [1.8–2.2 million]	170,000 [150,000–200,000]	0.6 [0.5–0.6]	77,000 [66,000–89,000]
Caribbean	240,000 [220,000–260,000]	20,000 [16,000–24,000]	1.0 [0.9–1.1]	12,000 [9,300–14,000]
Eastern Europe and Central Asia	1.5 million [1.4–1.7 million]	110,000 [100,000–130,000]	0.7 [0.6–0.8]	87,000 [72,000–110,000]
Western and Central Europe	850,000 [710,000–970,000]	30,000 [23,000–35,000]	0.3 [0.2–0.3]	13,000 [10,000–15,000]
North America	1.4 million [1.2–1.6 million]	55,000 [36,000–61,000]	0.6 [0.5–0.7]	23,000 [9100–55,000]
Oceania	59,000 [51,000–68,000]	3900 [2,900–5,100]	0.3 [<0.3–0.4]	2000 [1100–3100]
Global Total	33.4 million [31.1–35.8 million]	2.7 million [2.4–3.0 million]	0.8 [<0.8–0.8]	2.0 million [1.7–2.4 million]

## HIV in At-Risk Populations

### INJECTING DRUG USERS

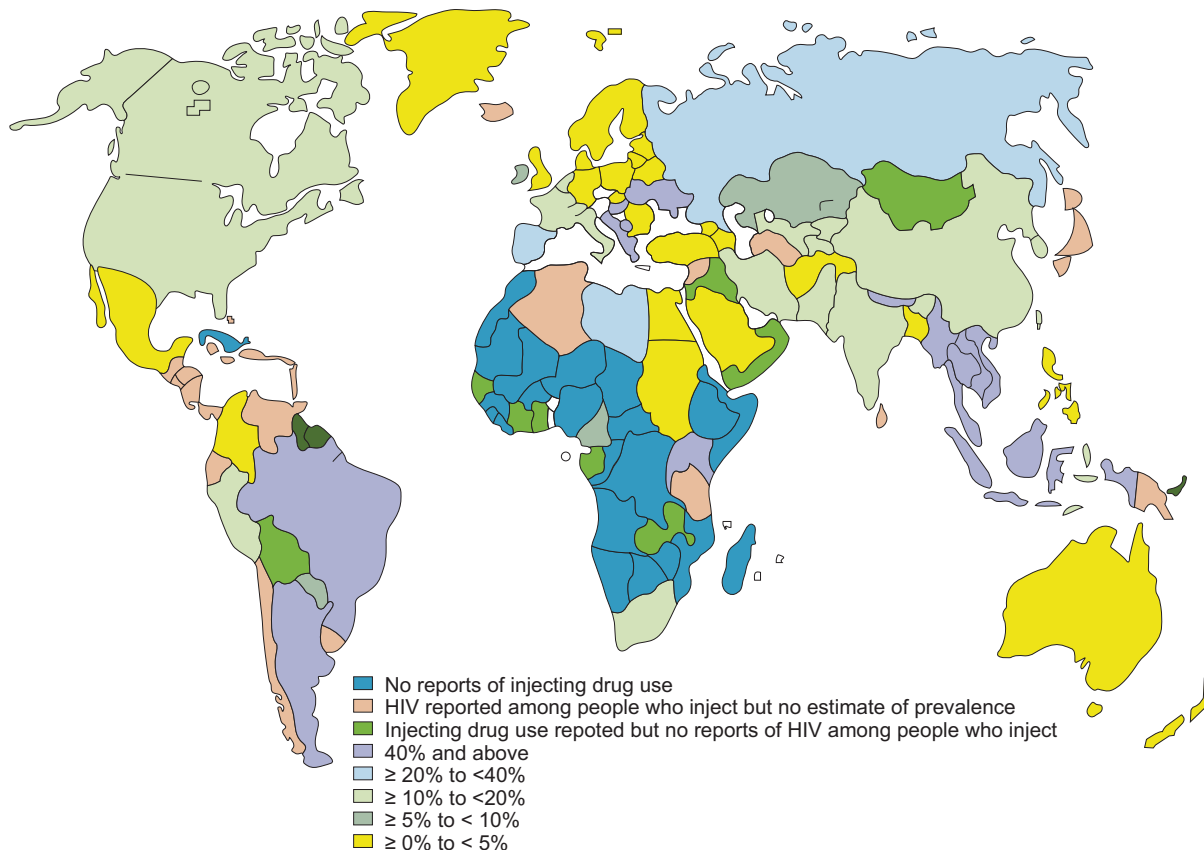

The sharing of contaminated equipment while injecting drugs is more efficient than sex at transmitting HIV, resulting in more rapid epidemics among injecting populations. Injecting is responsible for an increasing proportion of new HIV infections in many parts of the world, especially industrialized countries in Eastern Europe, South America and East and South-East Asia.<sup>45,46</sup> Countries that failed or were slow to introduce effective distribution systems for clean injecting equipment are particularly affected.<sup>47–48</sup> IDU is rare in Africa and thus has had a negligible role in the HIV epidemic in the region. IDUs epidemics are dynamic: for example, HIV was not identified among IDUs in Estonia a decade back whereas recent estimates show that the prevalence of HIV among IDU has reached around 72%.<sup>45</sup>

The findings of the Reference Group to the UN on HIV and IDU<sup>45</sup> show that:

- Globally, there are about 3.0 million (range 0.8–6.6 million) (Table 4.2) HIV positive IDUs, and HIV prevalence varies greatly between countries within the region and also within countries (Fig. 4.2).
- The national midpoint prevalence of HIV among IDUs ranged from less than 0.01% to 72% globally.
- Countries in South-East Asia, Eastern Europe and Latin America report a prevalence of above 40% in subpopulations of IDUs.
- China, Russia and USA have the highest populations of injectors and the prevalence of HIV in IDUs in all three countries is above 10%.
- There is a wide variation of HIV prevalence among IDUs within countries as well. For example, in China infection among IDUs is reported to be concentrated in 7 provinces only and in Russia the prevalence varies from 0.3% in Pskov to 74% in Biysk.

**Table 4.2:** Regional and Global Estimates HIV Positive IDUs, 2007<sup>45</sup>

Region	Estimated number of HIV positive IDUs
Eastern Europe	940,000 (18,500–2,422,000)
Western Europe	114,000 (39,000–210,500)
East and South-East Asia	661,000 (313,000–1,251,500)
South Asia	74,500 (34,500–135,500)
Central Asia	29,000 (16,500–47,000)
Caribbean	24,000 (6000–52,500)
Latin America	580,500 (181,500–1,175,500)
Canada and United States	347,000 (127,000–709,000)
Pacific Island States and Territories	500 (<250–500)
Australia and New Zealand	2500 (500–6000)
Middle East North Africa	3500 (1500–6500)
Sub-Saharan Africa	221,000 (26,000–572,000)
Extrapolated global estimates	2,997,500 (764,000–6,589,000)

**Fig. 4.2:** Prevalence of HIV among IDUs, 2007.<sup>45</sup>

## MEN WHO HAVE SEX WITH MEN

HIV prevalence rates are much higher in MSM than in general population globally (Box 4.2).<sup>49</sup> Over the past decade the incidence of HIV infection has resurged in MSM in the western world, and now there are reports of new or newly identified epidemics among MSM in Asia, Africa, and Latin America.<sup>50</sup> Testing has increased markedly in countries like USA, Canada, and the UK, which may at least partly explain the increase in diagnoses.<sup>51</sup>

Sex between consenting adult men remains criminalized in 85 countries as of 2007, including more than half of African states,<sup>49</sup> increasing the risk of HIV transmission as MSM are inaccessible to health education promotion. According to 2005 UNAIDS estimates less than 1 in 10 MSM globally have access to HIV prevention services.<sup>52</sup>

## SEX WORKERS

The prevalence of HIV in sex workers can vary considerably from country to country, within the same country, and from one type of sex worker to another. Differences in working environments, socioeconomic situation, health status, and knowledge and practice of protective measures explain some of this variation.<sup>53–54</sup> Because of their large numbers of sexual partners, sex workers in a number of countries were affected early in their country's HIV epidemics.<sup>38–40,55</sup> Since the sex industry's clientele is drawn from the population at large, often accounting for a substantial proportion of extramarital couplings,<sup>56–57</sup> the HIV prevalence among sex workers can to some extent foretell the impact of HIV in the general population. Interventions with sex workers that have proven effective at controlling HIV and other STIs include funded peer education, screening and treatment for other STIs, and the free distribution of condoms.<sup>58–61</sup> Such interventions

with sex workers have been estimated to be one of the most cost-effective HIV control strategies in developing countries.<sup>62–63</sup>

## MOTHER-TO-CHILD TRANSMISSION

Number of HIV infected children in the population depends on the prevalence of HIV in pregnant women and the availability of adequate prevention and treatment service to these women.<sup>21</sup> Majority of the 430,000 newly diagnosed children in 2008 acquired HIV through MTCT.<sup>64</sup> Multiple interventions are now available including: voluntary HIV testing of pregnant women, use of rapid testing at time of delivery and availability of antiretroviral therapy.<sup>8,21</sup> Availability of these interventions has reduced perinatal transmission all across Europe and North America.<sup>8,21,65</sup> The transmission rate has reduced in most high-income countries, from 25% to 1–2%.<sup>20</sup> However, transmission rates remains high in developing countries due to the limited availability of antiviral therapy, and difficulties with using formula milk.<sup>20</sup>

In 2005, only 9% of pregnant women were offered services to prevent HIV transmission to their newborns in middle and low-income countries.<sup>8,64</sup> MTCT remains a major problem in sub-Saharan Africa, in spite of the increased availability of antiretroviral drugs to pregnant women.<sup>43,66</sup> Similarly, a low percentage of pregnant women living with HIV have access to antiretrovirals in most parts of Asia.<sup>64</sup>

## OTHER MOBILE POPULATIONS

There are other at-risk populations that are often neglected when looking at the HIV picture. These populations include truck drivers, military personnel, and other mobile populations like refugees. HIV prevalence in military conscripts can give an indication of prevalence in the general population, as they come from all strata of general population.<sup>67</sup> Long haul truck drivers are also at high risk of HIV infection because of their large number of sexual partners, paying for sex, failure to use condoms, poor education, and lack of HIV knowledge.<sup>68–74</sup> Factors associated with increased risk of HIV for refugees include the prevalence of HIV in the host and refugee population, the prevalence of other STIs, level of sexual interaction between groups, availability of HIV prevention services, and specific risk factors like rape and sex work.<sup>75</sup>

## Regional Patterns of HIV

### SUB-SAHARAN AFRICA

Sub-Saharan Africa is the region most affected by HIV. An estimated 22.4 million people are living with HIV, including 90% of children living with HIV globally.<sup>43</sup> Approximately 2 million (1.7–2.3 million) died from HIV in the region in 2005.<sup>8</sup> Within sub-Saharan Africa, there is considerable variation between the HIV epidemics of various countries. National population-based surveys conducted between 2001 and 2008 revealed the adult national HIV prevalence is below 5% in most African countries. However, an HIV prevalence of greater than 15% was shown in 6 Southern African countries (Box 4.3).<sup>43</sup>

### Box 4.2 Prevalence of HIV in MSM in Various Regions<sup>50</sup>

- Europe: HIV prevalence in MSM ranges from 5% in Ireland to 18% in Spain in Western Europe, from 0% in Lithuania to 2.5% in Slovenia in Central Europe, and from 0% in Kazakhstan to 6% in Moscow in Eastern Europe and the former Soviet Union states.
- North America: According to the Centers for Disease Control and Prevention 48% of 1.1 million HIV positive people are MSM in the US. Similarly, in Canada half (51%) of people living with HIV are MSM.
- Oceania: MSM account for 64% of newly diagnosed and 82% of newly acquired infections in Australia. Whereas in New Zealand, 55% of HIV cases reported were MSM. In contrast only 0.1% of HIV infections are in MSM in Papua New Guinea.
- Asia: The prevalence varies widely among countries and within countries in Asia. In East Asia 33–67% of the newly reported HIV cases are MSMs. In South East Asia 0–31% MSM are infected with HIV and in South Asia 0.2–25% MSM are infected with HIV.
- Latin America: Prevalence varies from around 7% in Brazil and Nicaragua to 26% in Mexico. The average HIV prevalence among MSM across El Salvador, Guatemala, Honduras, Nicaragua, and Panama was 12%.
- Africa: The prevalence varies from around 11–38% in Kenya and 11–31% in Cape Town.

**Box 4.3** Countries with >15% HIV Prevalence in Southern Africa

- Botswana
- Lesotho
- South Africa
- Swaziland
- Zambia
- Zimbabwe

**Heterosexual Transmission**

High HIV prevalence and incidence rates in sub-Saharan Africa are mostly attributed to heterosexual transmission, leading to the region having the world's largest population of children living with HIV. Various studies, including population-based surveys, have shown a high prevalence of HIV serodiscordance among heterosexual couples in Africa, ranging from 2% in Rwanda to 13% in Lesotho and Zimbabwe.<sup>76–78</sup> A large proportion of heterosexual transmission occurs among serodiscordant couples.<sup>79</sup> One study using data from Demographic and Health Surveys (DHS) estimated that between 55% and 93% of new heterosexually acquired HIV infections among adults in urban Rwanda and Zambia occurred in the context of serodiscordant marital or cohabiting relationships.<sup>80</sup> A separate study using DHS data from 5 countries (Burkina Faso, Cameroon, Ghana, Kenya, and Tanzania) demonstrated that two thirds of HIV-infected couples were serologically discordant.<sup>81</sup> Furthermore, condom use was rare in countries such as Burkina Faso where almost 90% of cohabiting couples surveyed did not use a condom the last time they had sex.<sup>81</sup> Women and young girls are disproportionately affected by HIV in sub-Saharan Africa due to a number of factors such as physiological susceptibility and a number of social and legal disadvantages.<sup>43</sup> The ratio of women to men living with HIV is 3:2.<sup>8</sup>

**Injecting Drug Use**

Because IDU is rare in sub-Saharan Africa, it has had a negligible role in the HIV epidemic. Regardless, survey-based studies have shown that IDUs are at high risk of HIV infection in various countries, with prevalence reaching 12% in South Africa and 43% in Kenya.<sup>45</sup>

**Male Homosexuality**

Unprotected anal sex between men is an increasingly recognized risk factor for the HIV epidemic in sub-Saharan Africa.<sup>82</sup> Prevalence of HIV among MSM in sub-Saharan Africa has been listed in Table 4.3.

**Table 4.3:** Prevalence of HIV Among MSM in Sub-Saharan Africa

Kenya <sup>50,83–84</sup>	11–38%
Senegal <sup>50,85–86</sup>	21.5–22%
South Africa (Cape Town) <sup>50</sup>	11–31%
Sudan <sup>85–86</sup>	9%
Tanzania <sup>50</sup>	12%

**Mother-to-Child Transmission**

The percentage of HIV-infected women receiving antiretroviral drugs to prevent transmission to their newborn children increased from 9% in 2004 to 45% in 2008.<sup>66</sup> Although the number is decreasing, MTCT continues to account for a large number of new HIV infections in many African countries.<sup>43</sup>

**Sex Work**

Sex work is common but is now thought to contribute a smaller proportion of new HIV infections in sub-Saharan Africa where the epidemic is mature.<sup>63</sup> HIV is, however, prevalent among the sex worker population, with HIV prevalence reportedly greater than 30% in 7 African countries (Benin, Burundi, Cameroon, Ghana, Guinea Bissau, Mali, and Nigeria) and reaching 49% in Guinea Bissau.<sup>66</sup>

**ASIA**

In Asia, there were about 4.7 million people living with HIV in 2008, with an estimated 350,000 people who were newly infected and 330,000 deaths from an HIV-related illness.<sup>43</sup> The majority of the HIV infections in Asia occur in South and South-East Asia. Declines in adult HIV prevalence have been observed in Cambodia, where prevalence has fallen from 1.5% in 2001 to 0.8% in 2007. However, rapidly growing epidemics have been observed in Vietnam, Indonesia, Malaysia, and Pakistan.<sup>87</sup> In Indonesia, the number of people living with HIV more than doubled between 2001 (93,000) and 2007 (270,000).<sup>87</sup> This region has the world's most diverse spectrum of HIV transmission modes.

**Heterosexual Transmission**

Patterns of HIV transmission vary between countries in the region and also vary widely within countries. For example, in India heterosexual transmission drives the epidemic in the southern states, whereas IDU is mainly responsible in the north eastern states.<sup>88</sup> Condom promotion during commercial sex in Cambodia and Thailand have helped curb HIV spread through sexual transmission.<sup>67</sup>

**Injecting Drug Use**

IDU played a primary role in the HIV epidemics of several countries of the region.<sup>89</sup> During the late 1980s, the long-recognized centers of opium production known as the 'Golden Triangle' (in the bordering areas of Myanmar, Thailand, and the Lao PDR) and the 'Golden Crescent' (located in northwest Pakistan, the Badakhshan area of Afghanistan, and the Baluchistan area of Iran) began processing the drug into the injectable form, heroin.<sup>46</sup> The consequence in Asia was the twin epidemics of HIV and IDU during the 1990s.<sup>90–91</sup> These epidemics spread along overland heroin trafficking routes and through mobile populations, such as long distance truck drivers and migrants,

onto neighboring provinces of India and China. The injection of buprenorphine (another opiate) and methamphetamine (cheaper) subsequently increased in the region.<sup>90–91</sup> Outbreaks of HIV among IDUs occur rapidly and multifocally in their early stages<sup>38</sup> depending on factors such as frequency of sharing injecting equipment, local HIV prevalence, and the nature of drug-injecting networks.<sup>91</sup> Thus, the prevalence of HIV among IDUs ranged widely from 0% to over 90% in different settings within the region during the most recently available surveys.<sup>38–39,92</sup> While typically less than 1% of the general population is directly engaged in IDU, others can become exposed to HIV as sexual partners of injectors, both spouses and casual contacts, some of whom may be trading sex to purchase drugs.<sup>90,93</sup>

## Male Homosexuality

For majority of countries in the region, gay identity is largely considered to be a manifestation of Westernization,<sup>56,94</sup> even if tempered by local ethnic and economic forces.<sup>95</sup> In many parts of the region the practice of male-to-male sex is well documented in males for whom marriage and reproduction define a heterosexual social and sexual identity regardless of other behaviors.<sup>96</sup> In this context it can be difficult for surveillance programs to disentangle homosexual from heterosexual transmission of HIV even though male-to-male sex is common.<sup>56,96–97</sup> Male-to-male sex has not been widely addressed in behavioral surveys in the region.<sup>98</sup> In very populous countries such as China and India, there may be even more marked differences between urban and rural areas in HIV prevalence and in reporting of MSM behaviors<sup>49</sup> (Table 4.4).

**Table 4.4:** Prevalence of HIV Among MSM in Asia<sup>50</sup>

East Asia	
China	0.5–9%
Hong Kong	41%
Japan	67%
Singapore	34%
South Korea	33%
Taiwan	38.5%
South-East Asia	
Cambodia	0.7–9%
Indonesia	2–8%
Lao PDR	6%
Myanmar	29%
Thailand	17–31%
Vietnam	0–8%
South Asia	
Bangladesh	0.2%
Pakistan	3%
Nepal	3%
India	5–25%

## Mother-to-Child Transmission

HIV prevalence is increasing in antenatal clients in some parts of India.<sup>67</sup> In East, South, and South-East Asia, only 25% women of pregnant women living with HIV were receiving antiretrovirals for preventing MTCT in 2008.<sup>64</sup>

## Sex Work

The occurrence of female, male, and transgender prostitution has been extensively documented throughout Asia.<sup>39,41,56,94,99–103</sup> Migration within countries for the purposes of prostitution is ubiquitous.<sup>40,99,101,104</sup> International migration for the same purpose, a practice dating back centuries,<sup>101</sup> is also common. For example, Nepalese sex workers have long traveled to India; Shan women migrate from Myanmar to Thailand,<sup>101</sup> and Thai women to Japan.<sup>94</sup> Though prostitution is illegal in most Asian jurisdictions,<sup>40,94,99,105</sup> it is socially tolerated within many cultures and forms a significant part of local economies. In China alone there are believed to be over 3 million sex workers despite strict sanctions, with 1.5 million in India.<sup>41</sup> The “100% condom” program in Thailand, a national initiative intended to enforce condom use during all commercial sex encounters, has led to a declining HIV prevalence among sex workers in that country with clear benefits for their client base.<sup>103,106</sup> This success has encouraged neighboring countries to adopt similar programs.<sup>102</sup>

## EASTERN EUROPE AND CENTRAL ASIA

Until the mid-1990s, HIV was uncommon in this region.<sup>16</sup> Since then, HIV prevalence has increased significantly with an estimated 1.5 million people living with HIV in 2008.<sup>43</sup> The majority of those with HIV live in either the Russian Federation (69%) or Ukraine (29%) where the annual number of new HIV infection more than doubled between 2001 and 2007. The regional HIV epidemic is concentrated among IDUs. A large proportion of sex workers also inject drugs. Economic instability in parts of the region has fueled an increase in IDU, sex work, and migration, leading to the potential for the further spread of HIV in the region.<sup>16,107</sup> In the Eastern European region, changes in social attitudes to relationships and the role of family have led to liberal views on sex and substance use.<sup>107</sup>

## Heterosexual Transmission

Heterosexual transmission in the region is also rising in a steady fashion.<sup>21,88</sup> Of more concern is the growing proportion of new HIV infections that occur among women, contributing to 40% of new cases in Eastern Europe and Central Asia in 2006.<sup>108</sup> Only a minority of women was infected through use of contaminated drug injecting equipment, and most acquired HIV during unprotected sex with IDU partners.<sup>108</sup>

## Injecting Drug Use

IDU is the most important route of transmission of HIV in the region,<sup>65,88,107</sup> as injecting increased rapidly after the

collapse of Soviet Union and increasing production of opium in Afghanistan.<sup>21,107</sup> Estonia has the highest prevalence of HIV among IDUs in the world; approximately 72% of IDUs in the country are HIV positive.<sup>45</sup> There is wide variation in HIV prevalence in IDUs in Russia; from 0.3% in Pskov to 12.4% in Moscow, 32% in St. Petersburg, and 74% in Biysk.<sup>45</sup>

## Male Homosexuality

A small proportion of new HIV infections in this region are attributed to unprotected sex among men. In Eastern Europe, less than 1% of newly reported HIV cases are in MSM. In recent cross-sectional studies among MSM, the HIV prevalence ranged from 0% in Kazakhstan to 6% in Moscow in Eastern Europe and Central Asia.<sup>50</sup>

## Mother-to-Child Transmission

Effective antiretroviral treatment is now available to prevent mother-to-child HIV transmission in the region. Pregnant women are tested on a large scale in the Russian Federation and those with a positive confirmatory test must choose between abortion and prophylactic treatment.<sup>21</sup>

## Sex Work

There is an increasing frequency of STIs and IDU in the flourishing sex industry of the region, threatening to contribute to the spread of HIV.<sup>21</sup> Prevalence studies among sex workers have found significant levels of HIV infection in Russia, 15% among 123 prostitutes attending outreach programs in 2000 in Moscow and 17% among 192 injected-drug using prostitutes in 1999 in St. Petersburg.<sup>21</sup> However, the prevalence seems to be relatively low (around 2%) in rest of the region.<sup>109</sup>

## WESTERN AND CENTRAL EUROPE

The epidemic started in late 70s and early 80s in both Western and Central Europe.<sup>16</sup> In Western Europe 25,241 new cases were diagnosed in 2006 whereas 1,805 cases were diagnosed in Central Europe.<sup>110</sup>

## Heterosexual Transmission

Heterosexual transmission is the most common route of HIV transmission in both Western and Central Europe accounting for 54% and 52% of all new infections in 2006, respectively.<sup>110</sup> However, heterosexual transmission remains concentrated in specific subgroups of the population rather than the general population.<sup>109</sup>

## Injecting Drug Use

Injecting increased in the region in the 1990s as Eastern Europe and Central Asia acted as the drug trafficking routes for heroin from Afghanistan.<sup>21</sup> IDU accounted for 8% and 16% of new infections in Western and Central Europe in 2006, respectively.<sup>110</sup>

and injecting may be increasing in some countries including Italy, the Netherlands, and Spain.<sup>109</sup>

## Male Homosexuality

Throughout Europe there are wide differences in the prevalence of HIV among MSM in community settings, with a higher prevalence reported in those countries with larger and more visible MSM populations than in countries with smaller MSM populations.<sup>111</sup> HIV prevalence among MSM ranged from 5% in Ireland to 18% in Spain in Western Europe and from 0% in Lithuania to 2.5% in Slovenia in Central Europe.<sup>50</sup> According to Euro HIV, the number of new HIV cases in MSM almost doubled, from 2538 to 5016 during 1999–2006 in 13 Western European countries and similarly, in Central Europe, the number of new cases doubled although the actual number was small, 130 in 1999 to 295 in 2006. Homosexual transmission was responsible for more than 50% of all new reported cases in many Central European countries, such as Hungary, the Czech Republic, Slovakia, and Slovenia.<sup>50</sup>

## Mother-to-Child Transmission

Availability of perinatal HIV prevention programs has decreased the MTCT all across Europe.<sup>21,65</sup>

## Sex Work

In Central Europe, sex work has grown due to economic conditions and widespread criminality, and many sex workers are also IDUs.<sup>107</sup> Although the data on HIV prevalence among sex workers in Western Europe is very sparse, available data shows that prevalence is low (around 2%) among noninjecting female sex workers.<sup>109</sup> Male sex workers, transvestites, and migrant sex workers are more at risk of HIV.<sup>109</sup>

## LATIN AMERICA AND THE CARIBBEAN

The epidemic started in late 70s and early 80s in the region.<sup>16</sup> Sexual transmission and use of contaminated injecting equipment among the poor and unemployed remain the dominant modes of transmission.<sup>8</sup> The Caribbean has been profoundly affected by HIV with adult HIV prevalence higher than every other region outside sub-Saharan Africa.<sup>43,67,112</sup> A decline in the incidence of HIV has occurred in some Caribbean countries in the past decade and HIV prevalence has stabilized.

## Heterosexual Transmission

In Latin America the epidemic was initially in MSM and IDUs. However, there has been a substantial increase in heterosexual transmission in all countries of the region. In the Caribbean the main mode of transmission is heterosexual sex, often linked to sex work. In Latin America, women comprise 20–30% of HIV positive adults,<sup>65,88</sup> and in the Caribbean they comprise around 53%.<sup>88</sup>

## Injecting Drug Use

Although rare in most of the Caribbean, IDU is an important route of transmission in some countries of the region including Argentina, Brazil, Chile, Paraguay, and Uruguay and some parts of Mexico, Bermuda, and Puerto Rico.<sup>67,88</sup>

## Male Homosexuality

Recent studies in the Caribbean and Latin America have shown that HIV transmission is increasingly occurring among MSM in urban centers, with prevalence varying between 5% and 20%.<sup>113</sup> See Table 4.5 for prevalence in various countries. The HIV incidence in MSM in Central American countries was 5 per 100 person-years in 2007.<sup>50</sup>

## Mother-to-Child Transmission

Heterosexual transmission prevails in the Caribbean with an HIV prevalence of up to 8% in pregnant women in Haiti.<sup>65,88</sup> In Brazil, MTCT accounts for 90% of cases for children under 13 years; similarly, in Argentina 96% of cases among children are due to MTCT.<sup>112</sup>

## Sex Work

There has long been sex tourism in the Caribbean leading to the link between sex work and HIV. Migrant sex workers also represent a vulnerable population for HIV.<sup>114</sup> Multiple risk factors for HIV have been identified in the region among sex workers who also use drugs, including unprotected sexual activity with multiple partners, violent victimization and migration between high and low HIV prevalence areas.<sup>114</sup>

## NORTH AMERICA

The HIV epidemic started in late 70s and early 80s in North America.<sup>16</sup> In the US, most people with HIV have high level access to medical care.<sup>65</sup> Unsafe sexual practices among MSM and the use of contaminated injecting equipment remain the

major modes of transmission; however, an increase in heterosexual transmission has been seen in women and members of minority ethnic groups.<sup>8,65</sup>

## Heterosexual Transmission

Although almost three quarters (74%) of HIV positive people in the US are males, the proportion of women is increasing.<sup>8</sup> There is a large discrepancy between the prevalence rates among non-Hispanic Blacks and other racial/ethnic minority groups and the general population.<sup>115</sup>

## Injecting Drug Use

There has been a decrease in the proportion of HIV infections acquired through IDU. However, like other modes of transmission, HIV through injecting affects the racial and ethnic minorities disproportionately in the US.<sup>116</sup>

## Male Homosexuality

In both Canada and the US, almost half of the people living with HIV are MSM: 48.1% of 1.1 million HIV positive people living in the US in 2006<sup>117</sup> and 51% of 58,000 people living with HIV in Canada.<sup>50</sup> Out of the 56,300 new infections in the US in 2006, 53% were in MSM and out of the new infections in men, 72% were in MSM. Of new infections in MSM, 46% were in whites, 35% were in blacks, and 19% were in Hispanics.<sup>50</sup> Despite advances in HIV care, almost 6,000 MSM with HIV in the United States died in 2005.<sup>118</sup>

## Mother-to-Child Transmission

Multiple interventions like voluntary HIV testing of pregnant women, use of rapid testing at time of delivery and availability of antiretroviral therapy has decreased the MTCT tremendously, from approximately 1,700 per annum in the 1990s to 145 in 2002.<sup>8</sup>

## Sex Work

Sex work remains illegal in the United States except for a couple of counties in Nevada and the government of the United States takes a strong stance against sex work including declining all grants overseas aid to any HIV/AIDS projects that do not 'explicitly oppose' sex work.<sup>119</sup> Thus, little data is available for HIV in sex workers and their clients. Like Western Europe, HIV cases among sex workers in the US are attributed to injecting rather than sexual transmission.<sup>119</sup>

## MIDDLE EAST AND NORTH AFRICA

There is only limited data on the prevalence of HIV in the region. The epidemic started in the late 80s,<sup>16</sup> and the available data shows that HIV prevalence in Middle East and North Africa (MENA) is low, with national prevalences around 0.2%, except Sudan where the prevalence is estimated to be 2%.<sup>8,88</sup>

**Table 4.5:** Prevalence of HIV Among MSM in Latin America and Caribbean<sup>50</sup>

Bolivia	21%
Brazil	7–10%
Colombia	19%
Ecuador	15%
El Salvador	15%
Jamaica	32%
Mexico	26%
Nicaragua	8%
Paraguay	13%
Peru	10–22%
Trinidad and Tobago	20%

## Heterosexual Transmission

The main mode of transmission in the region is heterosexual contact.<sup>8,88</sup> Although sexual behavior data remains limited; multiple partnerships, premarital and extramarital relationships, casual sex, and contact with female sex workers are reported in most countries with significant variations that affect sexual transmission.<sup>120</sup>

## Injecting Drug Use

There has been increasing IDUs in the region because of the changing drug-trafficking routes.<sup>121</sup> Injecting as the mode of transmission is increasing in some countries especially Iran and Libya,<sup>88,120</sup> and also Bahrain, Algeria, Egypt, Kuwait, Morocco, Oman, and Tunisia.<sup>121</sup> Overall, HIV prevalence among IDUs is in the low to intermediate range, 0.2% of population in the region, compared to global figures.<sup>120</sup>

## Male Homosexuality

Little is known about the prevalence of HIV among MSM in MENA, as it is strictly prohibited in most countries on religious grounds. In Sudan, the prevalence ranged between 8% in insertive MSM and 9% in receptive MSM, and it was 6% in MSM in Egypt.<sup>50</sup>

## Mother-to-Child Transmission

In the MENA region below 1% of pregnant women are HIV positive.<sup>120</sup> Less than 200 pregnant women infected with HIV received antiretroviral treatment out of an estimated number of 13,400 HIV-infected pregnant women in 2008.<sup>64</sup>

## Sex Work

Sex work is a hidden trade in most MENA countries due to religious and government laws. Thus, data on HIV prevalence in sex workers is very difficult to obtain. Prevalences of 0.1% to 1% among adult female sex workers have been reported.<sup>120</sup> In Djibouti sex work is less hidden compared to the rest of the region.<sup>121</sup>

## OCEANIA

The epidemic started in late 70s and early 80s<sup>16</sup> and the overall HIV prevalence in Australia, New Zealand, and Fiji remains low at or below 0.1%. However, the epidemic in Papua New Guinea is growing rapidly with the number of people infected with HIV increasing about 30% per year since 1997.<sup>8</sup>

## Heterosexual Transmission

In Australia, only 20% of HIV infections were due to heterosexual transmission between 2000 and 2006, up from 15% between 1993 and 1999.<sup>122</sup> Casual and commercial sex, mostly heterosexual is driving the epidemic in Papua New Guinea and rape, sexual

aggression, and other forms of violence against women is aiding the epidemic.<sup>67</sup>

## Injecting Drug Use

Levels of HIV are very low (<1%) in IDUs in Australia and New Zealand despite a relatively higher prevalence of injecting; this is because of the geographic isolation and the early introduction of needle and syringe, targeted education, and opiate substitution programs.<sup>45</sup>

## Male Homosexuality

In Australia and New Zealand, HIV continues to be an infection that disproportionately affects MSM<sup>51,67,122</sup> and a 2008 study shows that HIV prevalence in homosexual men in large Australian cities is now less than 10%.<sup>51</sup> In 2005, 76% of new HIV diagnoses and 88% of newly acquired HIV infections were in MSM.<sup>51</sup> HIV prevalence among MSM is estimated to be 1% in 2007 in New Zealand, and 5.5% of the 2,872 reported HIV cases during 1985-2007 were in MSM.<sup>50</sup> In Papua New Guinea 0.1% of the total of reported HIV infections were in MSM.<sup>50</sup>

## Mother-to-Child Transmission

In Papua New Guinea, 1% of pregnant women tested HIV positive at antenatal clinics in Port Moresby and 2.5% of pregnant women were HIV positive in Lac in the Central Highlands.<sup>67</sup>

## Sex Work

The overall prevalence of HIV among the sex workers was more than 10 times than that of the general population in Papua New Guinea.<sup>123</sup> HIV is rare (<1%) among female sex workers in Australia and New Zealand because of high condom use at work and the low prevalence of HIV in IDUs.

## Conclusion

HIV morbidity and mortality continues to increase in many parts of the world despite major advances in the understanding of HIV in the past two decades and increasing access to antiretroviral treatment.<sup>8</sup> HIV has become one of the leading causes of premature death in men and women aged 15–59 years.<sup>8</sup> The following interventions have been suggested for limiting the impact of HIV in developing countries<sup>65</sup>:

- Strengthened HIV surveillance
- Life skills (including HIV) education for youth
- Widespread voluntary testing and counseling
- Health education, condom promotion, and strengthened STD control, including special programs for sex workers
- Blood safety
- Prevention of perinatal transmission
- Treatment services for drug users (including provision of sterile injection equipment)
- Appropriate HIV care

- Strengthened tuberculosis control
- Strengthened education of girls, promotion of women's rights and status
- Services for orphans

### Summary

HIV infection spreads through three major routes: sexual, blood borne, and mother-to-child. Most infections are caused by the type 1 virus, which is divided into three groups based on the genome difference: M, N, and O. There were an estimated 33.4 million people living with HIV in 2008; with an estimated 2.7 million new HIV infections (2.3 million adults and 0.4 million children below 15 years) and 2 million (1.7 million adults and 0.3 million children below 15 years) deaths in the year. Sub-Saharan Africa is disproportionately affected by HIV and 70% of the deaths associated with the infection in 2008 were in the region with many countries having an HIV prevalence of more than 15%. Different modes of transmission and different at-risk populations drive the epidemic in various parts of the world. Injecting is responsible for an increasing proportion of new HIV infections in industrialized countries in Eastern Europe, South America, and East and South-East Asia. HIV has resurged in MSMs in the western world over the past decade with increasing reports of new or newly identified epidemics among MSM in Asia, Africa, and Latin America. The prevalence of HIV in sex workers varies considerably from country to country, within the same country and from one type of sex worker to another; this is explained by the differences in working environments, socioeconomic situation, health status, and knowledge and practice of protective measures. Briefly, HIV morbidity and mortality continues to increase in many parts of the world despite major advances in the understanding of HIV in the past two decades and increasing access to antiretroviral treatment.

## Sexual Behavior and Sexually Transmitted Infections

Kaye Wellings

### Introduction

An understanding of trends and patterns in sexual behavior is essential to the prediction and prevention of STI transmission. Reliable data are needed to understand the epidemiology of sexually transmitted infections, to design effective interventions aimed at reducing transmission, and to assess progress towards these goals. Data from comparative studies are vital in guiding the effective targeting and tailoring of interventions to specific social groups and contexts. Importantly, too, empirical evidence is needed to correct myths in public perception of behaviors. In this chapter, we describe current trends and patterns in sexual behavior and their implications for the prevention of STI transmission.

### Trends and Patterns of Sexual Behavior

The past half century has seen marked changes in sexual behavior. These have occurred in response to demographic changes: in the age structures of populations, in the timing of marriage, and in the size of families. The scale of mobility and migration between and within countries has increased. The increase in intra and international travel, particularly, has played its part in increasing possibilities for the transmission of STIs, but so too have changing patterns of labor, rural to urban movement, and social disruption due to war and political instabilities.

Attitudes towards sexual behavior have changed significantly in recent times. Global communications, including the internet, have had a bearing on social norms, transporting Western sexual images to more conservative societies, particularly those in which advances in information technology have been rapid. The increasing accessibility of pornography has provided new imagery surrounding sexual practices and relationships.<sup>1</sup> Public health policy and practice has also impacted on sexual behavior. Advances in contraception have increasingly freed sexual expression from its reproductive consequences; access to sexual health services has increased and few areas have been unaffected by efforts to prevent HIV transmission. The HIV epidemic has significantly influenced the context in which sexual behavior occurs, providing the impetus to public discussion of sexual matters, to research

on the subject, and to innovation in interventions designed to improve sexual health.

### RISK BEHAVIORS

Given the rapid pace of social change, sexual behavior has perhaps changed less over time than might have been supposed. The widespread assumption that onset of sexual activity is occurring at ever younger ages, for example, is not borne out by the evidence. Considerable public health interest surrounds age at onset of sexual activity, since early sexual intercourse is more likely to be nonconsensual, to be regretted, to be unprotected against unplanned pregnancy and infection, and to be associated with larger lifetime numbers of sexual partners.<sup>2-4</sup> The evidence of an association between age at sexual debut and risk of sexually transmitted infections after adjusting for numbers of life time sexual partners, is equivocal, but has been demonstrated in some studies.<sup>5</sup>

Cross-nation comparisons show marked regional and gender variations in the age at which sexual activity begins but no universal trend toward earlier sex, at least for women.<sup>6</sup> In countries in which first intercourse still occurs predominantly within marriage, the tendency towards later marriage has been accompanied by a trend towards later sex among young women. For women, median age at first intercourse is lower in regions in which early marriage is the norm, for example, in South Asia, Central, West and East Africa, and higher in Latin America and in some countries of the Middle East and South-East Asia. For men, age at first intercourse is, in general, not linked to age at marriage. In most African and Asian countries men start sex later than women. Gender differences are less pronounced in the richer countries of the West. In industrialized countries, sexual activity before age 15 has become more common in recent decades but the prevalence is low.

The shift toward later marriage has led to an increase in premarital sex,<sup>7</sup> the prevalence of which is higher in high-income than low- and middle-income countries, and among men compared with women<sup>8</sup> (Fig. 5.1a,b). Marriage is often held to be a protective factor in relation to STI transmission, yet marriage

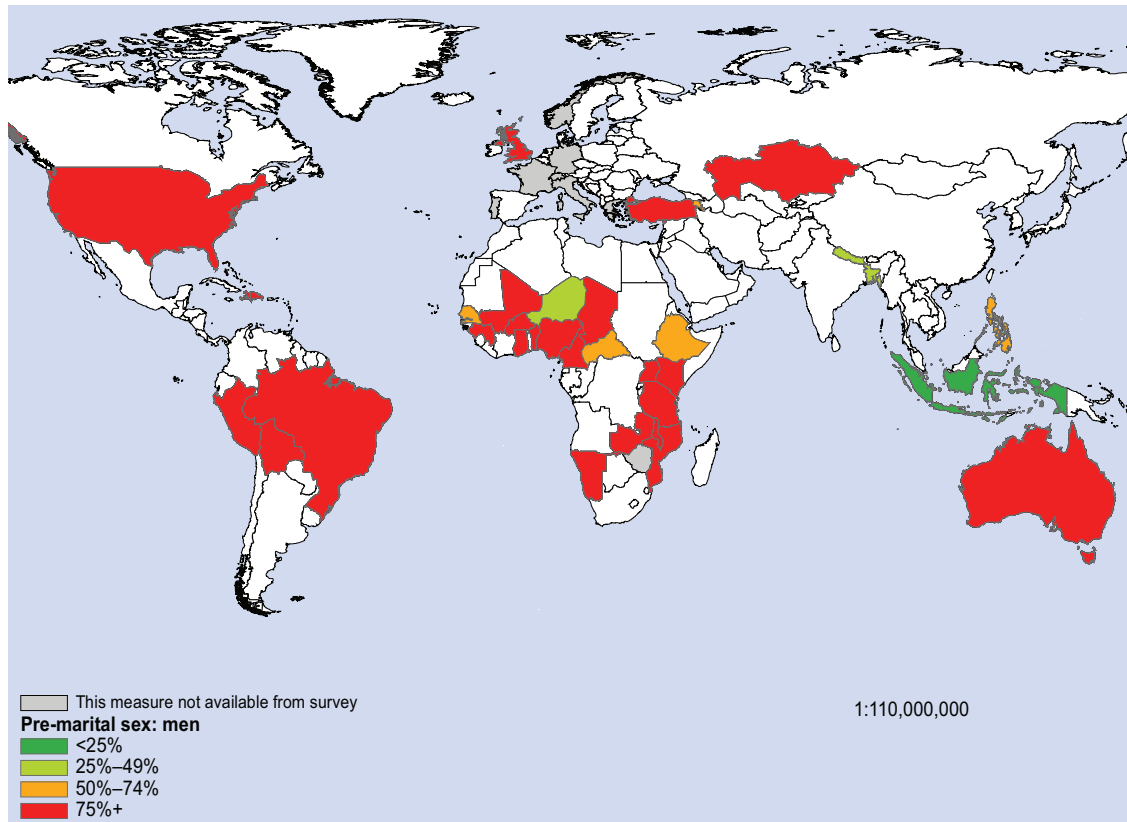

Fig. 5.1a: Prevalence of premarital sex among men.

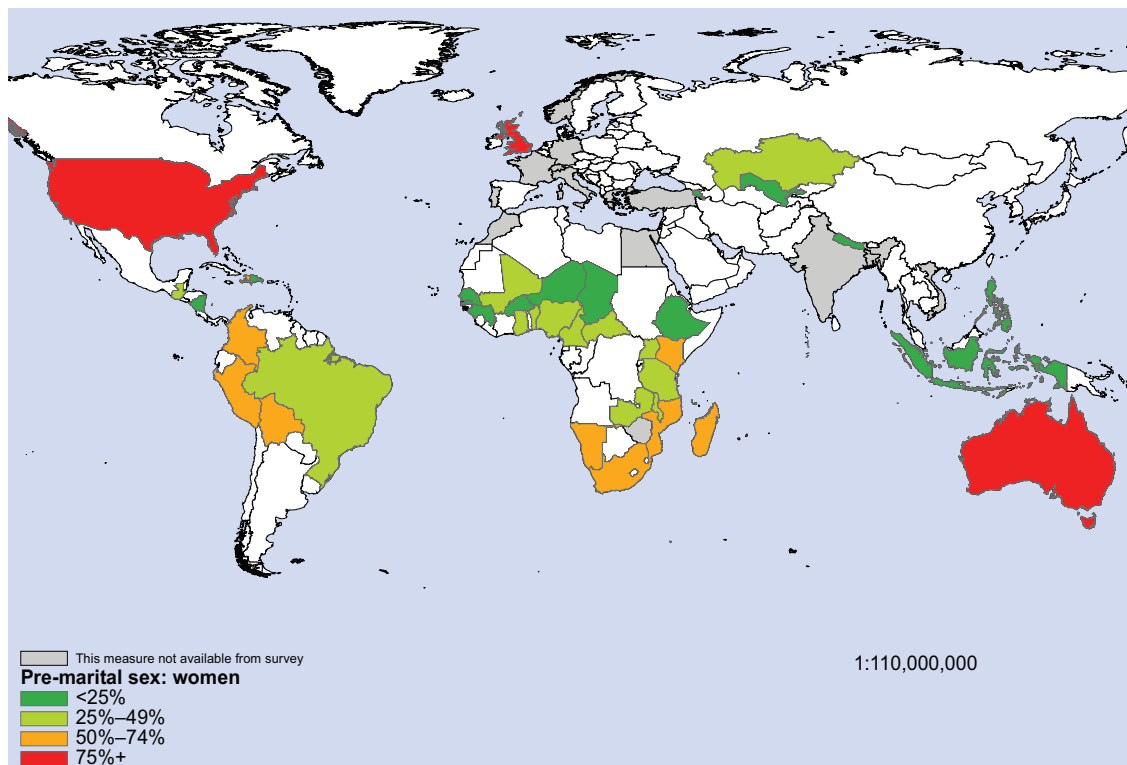

Fig. 5.1b: Prevalence of premarital sex among women.

does not necessarily ensure safer early sexual experience. In Kenya and Zambia, for example, research has shown that the sexual health benefits of marriage for women were offset by higher coital frequencies, lower rates of condom use and their husband's risk behavior.<sup>9</sup> Married women may find it more difficult than single women to negotiate safer sex and fewer use condoms for family planning. In Asian countries where early marriage is encouraged to protect young women's honor, early sexual experiences can be coercive and traumatic.<sup>10,11</sup>

Despite the prevalent view that sexual activity is highest in young single people, the evidence is that married people have the most sex. Sexual activity among those who are single tends to be sporadic and, in most regions, well under half of unmarried non-virgins report having had sex in the last month. Single men and women in many countries in Africa are relatively inactive sexually, in marked contrast to those in industrialized countries where two-thirds and three-quarters, respectively, report recent sexual activity.<sup>6</sup>

Multiple partnerships are a key risk behavior for STIs. The majority of people report only one sexual partner in the past year; only a minority of men and women report multiple partnerships in that time period. The prevalence of multiple partnerships varies regionally but is notably higher in industrialized countries.<sup>6</sup> Having two or more sexual partners in the past year is more common among men than women, and reported levels are higher in industrialized countries. Only in some industrialized countries are men and women more equal in the proportions

reporting multiple partnerships. Some of the gender difference is attributable to reporting bias. In countries like Africa, for example, in which young people greatly outnumber older people, the difference can be largely explained by the age structure and patterns of age mixing, that is, older men having sex with younger women (Fig. 5.2a,b,c). Median age differences between spouses in Africa are comparatively long. Age mixing may be an important determinate of STI/HIV prevalence in adolescents and indeed one of the few risk behaviors shown to be associated with increased prevalence in heterosexual<sup>12</sup> and homosexual<sup>13</sup> encounters is having an older male partner.

In some countries of South America such as Brazil, however, more men than women report having one or more recent sexual partners in all age cohorts. There the median age difference between partners is shorter and patterns of age mixing and age structure do not account for the gender differences in sexual partnerships. The Latin "macho" culture may encourage men to over report, and women to under report, sexual activity.

In this context, we need to distinguish between lifetime sexual partnerships conducted serially and concurrent partnerships. Concurrent sexual partnerships play a fundamental role in accelerating the spread of STIs and HIV.<sup>14–18</sup> Defined as those in which one or both of the partnership members have other sexual partners while continuing sexual activity with the original partner, concurrent partnerships have been shown to permit more rapid spread of STIs than the same rate of new sequential partnerships.<sup>16</sup>

**Fig. 5.2a:** Population distribution by age and sex and number of sexual partners in the past year, 15–49 year olds (Brazil).

**Fig. 5.2b:** Population distribution by age and sex and number of sexual partners in the past year, 15–49 year olds (Britain).

**Fig. 5.2c:** Population distribution by age and sex and number of sexual partners in the past year, 15–49 year olds (Uganda).

Concurrent sexual partnerships have been most strongly associated with the transmission of bacterial sexually transmitted infections. Viral sexually transmitted infections such as

human papillomavirus (HPV),<sup>18</sup> and *Chlamydia trachomatis* have, however, also been shown to be associated with partner concurrency.<sup>19</sup> Concurrency facilitates transmission by shortening the time between sexual contacts among infected and susceptible persons, particularly during the highly infectious period.<sup>20</sup> But other factors associated with concurrency, such as type of relationship,<sup>20,21</sup> disassortative mixing,<sup>20,21</sup> higher levels of unprotected sex,<sup>16,18</sup> and the use of alcohol and other drugs<sup>18</sup> also play a part. Unfortunately, the comparative empirical data seldom capture whether partnerships are conducted concurrently or serially. However, there is evidence to show that although lifetime numbers of sexual partners may be lower in some African countries, concurrent relationships may be more common and of longer duration than in other regions.<sup>22–25</sup>

Intimate partner violence has also been shown to increase the risk of sexually transmitted infections, through decreased autonomy and inability to ensure condom use, principally on the part of women.<sup>26</sup> Understanding the link between violence and inability to use condoms contributes to an understanding why some sex worker populations are particularly vulnerable to elevated rates of STI infection compared with the general population.<sup>27,28</sup>

Estimates of lifetime prevalence of sexual violence by an intimate partner from the WHO study on gender-based violence range between 10% and 50%.<sup>29</sup> There is an association between early sexual experience and sexual violence; in more than half the WHO settings, over 30% of women who reported first sex before the age of 15 years described having been forced to do so and three quarters of women who had been abused since the age of 15 identified the perpetrator as their intimate partner.

The apparent lack of association between regional variation in sexual behavior and regional variation in sexual health status, and in particular, the comparatively high prevalence of multiple partnerships in the West compared with parts of the world with far higher rates of STIs and HIV, for example African countries, may appear counterintuitive. It is likely to be explained partly by higher rates of concurrency in some countries, but also by lower rates of condom use. The predominant form of risk reduction practice in relation to STIs, condom use, has increased in prevalence almost everywhere—in some cases, for example, Uganda, dramatically so. In industrialized countries too, the rise in condom use has been impressive. Yet rates of use are still low in many developing countries and this is likely to be attributable to factors relating to access and service provision. Even in the richer countries prevalence of use is not sufficiently high to offset the risk posed by increases in the prevalence of other risk behaviors.<sup>30</sup> There are few comparative data on the consistency with which condoms are used. Men and women who report concurrent sexual partners are more likely to report more recent episodes of unprotected sex<sup>18</sup> and their increased risk of STI transmission may be compounded by the low prevalence of condom use.<sup>16</sup>

## RISK GROUPS

In general, a focus on behaviors rather than groups is more useful in a public health context, since risk behaviors are not necessarily limited to the groups thought of as high-risk, and the changing behavior of men and women with situation defies efforts to position them discretely into groups. Many men who have sex with men (MSM), for example, also have sex with women and those who do are less likely to practice safer sex.<sup>31</sup> An individual's risk depends also on their partner's risk. Monogamous women in many parts of the world are rendered more susceptible to sexually transmitted infection on account of their partner's risk behavior, yet may be unable to negotiate condom use.<sup>32</sup>

Nevertheless, although STIs can be contracted by all sections of society, some identifiable groups are more vulnerable than others. Young people, MSM and men and women affected by poverty and social exclusion are disproportionately affected. A major problem for intervention research is that, as a general rule, the higher the risk in terms of STI acquisition, the greater the challenges in terms of effective sampling and data collection.

MSM, a particularly high-risk group for HIV and other STIs, are a case in point. The socially censored nature of same sex activity may lead to under reporting and may also account for its absence from the research agenda. A recent review of the prevalence of same sex activity among men, for example, identified 67 studies,<sup>33</sup> yet none were from Africa, the Middle East, or the English speaking Caribbean.

Clients of sex workers are important bridging groups in the transmission of STIs and HIV to wider sexual networks. Transactional sex<sup>1</sup> may be a factor explaining the fact that men are more likely to report concurrency than women.<sup>18</sup> In countries with wide gender differences between men and women in the prevalence of premarital sex, young men are more likely to report sex with sex workers.

Mean numbers of sexual partners are not surprisingly higher among male and female sex workers. Moreover, female sex workers are often exposed to violence, and those who are have diminished capacity for harm reduction and have greater prevalence of STI symptoms.<sup>34</sup> However, the primary risk for STIs among sex workers is unprotected sex with high-risk regular partners.

The use of different definitions of sex work makes it difficult to make comparisons of the prevalence of transactional sex across time and place. The continuum of sexual exchange ranges from expectation of gifts or favors within personal relationships, to more formal trading of sex for money. Estimates of the proportion of men who are clients of sex workers range from 1%–14% in different regions.<sup>33</sup> The proportion of men reporting having obtained “sex in exchange for money, gifts, or favors” in the past year is highest in countries of Central and Southern Africa (medians: 13.6% and 11.3%, respectively), followed by Eastern and West Africa (9.8% and 8.9%, respectively). More recent African surveys using a more restricted definition of “paying for sex” have reported lower prevalences. Estimates in other areas, Latin America, Eastern Europe, Central Asia, and West European countries were below 3%.<sup>33</sup>

## IMPORTANCE OF SOCIAL CONTEXT

The variation in patterns of sexual behavior, between regions and between sub-groups of the population, reflects the powerful role of environmental factors in shaping behavior and its consequences for sexual health. The striking gender differences in sexual behavior, for example, are largely determined by social norms in specific cultural contexts. Differences between men and women in terms of sexual behavior are most pronounced in the less industrialized countries.<sup>6</sup> Men report more premarital sex and multiple partnerships than women in all but the more industrialized countries. The sexual double standard, whereby restraint is expected of women, while excesses are tolerated for men, compounds sexual health problems for both men and women. Women may be disadvantaged in protecting their sexual

\*In addition to the formal trading of sex for money, sex may be exchanged for gifts or favors within personal relationships, and hence the term “transactional sex” is sometimes preferred.

health where their partner is senior to them in age and/or superior in status; and where they are beholden to a man for favors, goods, or money in return for sex.

Poverty, deprivation, and unemployment also contribute to personal risk. Lack of local employment opportunities may drive men and women to sell sex or travel greater distances to work.<sup>35</sup> Being away from home is associated in both developed and developing countries with concurrent partnerships, disruption of existing partnerships and an increase in risk behaviors.<sup>36–38</sup>

Possibly, the most powerful influences on human sexuality are the social norms governing its expression. Morals, taboos, laws, and religious beliefs employed by societies the world over circumscribe and radically determine the sexual behavior of their citizens. Such strictures may have been instituted to protect well-being and rights, yet they may also hinder attempts by both men and women to protect their sexual health, and they also strongly influence the selection of acceptable public health messages. In some countries, Brazil for example, condoms are available to young people in schools; in others, parts of Indonesia for example, possession is a criminal offence.

Nowhere are the social norms more strongly felt than in the area of homosexual activity. In some parts of the world, sex between men can be celebrated in public parades of pride, in others it carries the death penalty. Whether sexual orientation is innate is an issue that is hotly contested in scientific circles, but more important from a public health perspective is the issue of sexual identity, a term used to refer to the way in which an individual sees himself and is seen by others. Where cultures stigmatize homosexual behavior and relationships, men and women may be wary of assuming an openly gay identity. Behaviors that are discriminated against may be driven underground, thwarting public health initiatives to protect sexual health.

## Implications for Interventions to Improve Sexual Health

Sexual behaviors present particular challenges to public health. The practices involved are for the most part personal and private, and they are often stigmatized and discriminated against. This has consequences for prevention of STIs at a number of levels. Men and women may feel unable to talk about safer sex; they may feel disinclined to seek help; politicians may be unwilling to support provision of services for some populations; and service providers may feel unable to reach those in greatest need of help, or have negative attitudes towards them.

Where behaviors are criminalized, they present even greater challenges for intervention. In general, laws protect the young and those vulnerable to coercion and exploitation, but they may also impede safer sex practices.<sup>39</sup> Illegal practices are more likely to be engaged in a furtive or clandestine manner, and opportunities for protection are constrained. In most parts of the world, for example, aspects of sex work are criminalized. As a result, sex workers have little legal protection and may easily be exploited or abused by clients, coworkers, and law enforcement officials.<sup>28</sup> The isolation and disempowerment of sex workers, enforced

by the threat of violence, may create barriers to negotiating safe sex practices, thereby increasing the risk for STIs. The success of preventive strategies may therefore depend, not only on acceptance of sexual practices which are socially censured, but it may also depend on more radical action, on engaging with policy and law makers to effect shifts in social norms and, in some instances, in influencing legislative reform. Condom use is uncommon among sex workers in India<sup>40</sup> for example, where commercial sex is heavily socially proscribed, but is near-universal in Mexico,<sup>41</sup> where public health agencies have actively and openly engaged in cooperation with female sex workers.

Interventions encouraging adoption of risk reduction practices remain a cornerstone of sexual health promotion but the evidence is that they need to be targeted and tailored to individual needs and circumstances to be effective. Multiple messages are needed, which respect diversity and preserve choice. A focus on enabling young people to have sex only when they are ready to do so has obvious value, given the evidence that first intercourse is retrospectively regretted by many women, and some men. Yet, abstinence may not be an appropriate message for those for whom first sexual experience is not consensual, where the sexual abuse of young people is common, and where the need for survival may force young people to sell sex. Effective intervention design will also focus on behaviors, rather than identity.

The strong contextual influences on sexual behavior have clear implications for intervention. Given the diversity of sexual behavior, a range of preventive strategies are needed to protect sexual health. Approaches are needed that focus not only on motivating individual behavior change, but also on the social context in which sex occurs. Although influencing individual risk behaviors is crucial to improving sexual health, efforts are needed to address the broader determinants of sexual behavior, particularly those relating to the social context. Comprehensive behavioral interventions are needed that take account of the social context in mounting individual level programs; attempt to modify social norms to facilitate uptake and support maintenance of behavior change; and tackle the structural factors contributing to risky sexual behavior. The diversity of sexual behavior needs to be respected in a range of approaches tailored to whole societies, and to particular groups and individuals within them.

# Surveillance for Sexually Transmitted Infections and HIV

Rebecca Guy

## 6

### Introduction

The primary role of public health surveillance is to guide the planning and evaluation of policy and programs, through the collection, analysis, and interpretation of various forms of statistical information.<sup>1</sup> This chapter focuses primarily on HIV, syphilis, gonorrhea, and chlamydial infection, and the syndromes they cause, as these pathogens are the main focus of HIV/STI control programs. It is generally considered to be a role of governments to plan and fund surveillance systems, but it is also understood that they do so through various forms of partnership with community agencies who collect, interpret, and make use of surveillance data. Surveys for HIV prevalence or HIV-related risk behavior may be undertaken by public health agencies, or by research teams working in parallel to, or on behalf of government.

### Important Attributes of Surveillance

Guidelines and recommendations for HIV surveillance have been developed by several organizations over the past 2 decades, including the World Health Organization (WHO),<sup>1–3</sup> United States Centers for Disease Control (CDC),<sup>4–6</sup> and Family Health International.<sup>7</sup> CDC has also published guidelines that are widely used in the evaluation of surveillance systems and provide a framework for assessing systems against a number of criteria, including but not limited to simplicity, accuracy, representativeness, timelessness, and acceptability (Box 6.1).<sup>4</sup> These criteria are important from a technical perspective, but the value of a surveillance system is ultimately judged by the extent to which it fulfils its objective of guiding programs and policy.<sup>1</sup>

#### Box 6.1 Examples of Key Surveillance Attributes

### Information Collected by Surveillance Systems

HIV and STI surveillance provide routine information on key indicators that can guide the planning and evaluation of initiatives intended to reduce HIV and STI transmission. There are many different forms of information that may be of relevance to this task and a variety of ways in which such information might be collected. The prevention of HIV and STI transmission relies on a number of public health strategies, including education, distribution of condoms and clean needles, clinical services to diagnose and treat genital infections, and the provision of HIV testing.<sup>8</sup> These strategies have been endorsed by international organizations such as UNAIDS and WHO,<sup>8</sup> as well as many national governments. Their implementation can be monitored at several levels:

- *Process indicators* provide information on the extent to which each strategy is being implemented. At the most basic level, process indicators record funds allocated, numbers of staff employed, staff or units of prevention supplies distributed.<sup>9</sup>
- *Outcome indicators* are a second level of monitoring and look at the outcomes of the strategy, as would be illustrated by the proportion of people who regularly use condoms or HIV and STI knowledge and attitudes.<sup>9</sup>
- *Impact indicators* are the third and most important level of monitoring and focus on the impact of the strategy, as might be reflected in the number of new HIV and STI infections that are occurring in the population under surveillance.<sup>9,10</sup>

Ideally, information at all 3 levels should be available before, during, and after the implementation of a prevention strategy. The information collected prior to implementation can provide the basis for planning the implementation, while the information obtained during and after implementation allows the strategy to be evaluated in various ways.<sup>9</sup> It is important to note that a number of indicators are monitored on an ongoing basis by routine surveillance systems, and their measurement is not necessarily synchronized with the implementation of a specific prevention strategy.

Guidance on the construction of core indicators is described in various monitoring and evaluation documents.<sup>9,10</sup> These indicators will vary according to whether the country is considered to have a generalized or concentrated/low-prevalence epidemic as defined in the UNAIDS guidelines for second-generation surveillance.<sup>1</sup> In very early stages, when HIV infection is at low levels, it makes sense to focus attention on monitoring the potential transmission via surveys of sub-populations with risk behavior,<sup>1</sup> monitoring sexually transmissible infections (STIs) and other biological markers of risk,<sup>1</sup> tracking levels of testing to make sure that people at risk will be diagnosed if they acquire infection and routinely recording new diagnoses of HIV infection.<sup>1</sup> If transmission appears in particular population groups, such as injecting drug users or MSM, reflecting so-called “concentrated” epidemics, then it is necessary for HIV and behavioral surveillance systems to be put in place to allow the appropriate measurement of program indicators in these groups and populations to which they are epidemiologically linked. There may not need to be a strong focus on the wider population, although cross-sectional surveys of behavior in the general population and monitoring of HIV prevalence in populations such as antenatal women in urban areas could be conducted.<sup>1</sup> In so-called “generalized” epidemics, when the overall population prevalence exceeds 1%, broader surveillance measures are called for, which may involve monitoring of HIV prevalence in antenatal women on a routine basis in both urban and rural areas and cross-sectional surveys of behavior in the general population.<sup>1</sup> Depending on the nature of the epidemic, these activities may also be supplemented with the monitoring of populations at higher risk.<sup>1</sup> Data on morbidity and mortality are also important in generalized epidemics to provide an indication of overall public health outcomes.<sup>1</sup> Table 6.1 provides some examples of the 2006 national commitment and action indicators according to the HIV epidemic type.

**Table 6.1:** Examples of HIV/STI Prevention Program Indicators for Concentrated/Low-prevalence Countries<sup>10</sup>

Type of indicator	Concentrated/low-prevalence countries	Generalized epidemics
Process indicators	Percentage (most-at-risk populations) reached by prevention programs	Percentage of schools with teachers who have been trained in life-skills based HIV education and who taught it during the last academic year
Outcome indicators	Percentage of men reporting the use of a condom the last time they had anal sex with a male partner	Percentage of young women and men aged 15–24 reporting the use of a condom the last time they had sex with a nonmarital, noncohabiting sexual partner
Impact indicators	Percentage of (most-at-risk population(s)) who are HIV infected	Percentage of young women and men aged 15–24 who are HIV infected Percentage of infants born to HIV infected mothers who are infected

## Measurement of Outcome and Impact Indicators through Surveillance Systems

### TYPES OF SURVEILLANCE SYSTEMS

The indicators needed to monitor HIV and STI prevention initiatives can be obtained through routinely collected health information systems, or data collection systems that are put in place specifically for the purpose of monitoring. A third, hybrid approach involves supplementing routinely collected health information with additional data collection in designated areas of interest. In the following sections, the main surveillance approaches are described, and their relative strengths and weaknesses assessed.

### Routine Case-Reporting

The most widely used surveillance mechanism for infectious disease, including STI, HIV infection, and AIDS, is based on the routine reporting of newly diagnosed cases to a central public health unit, either by legal requirement or by agreement.<sup>1</sup> The case reporting may be conducted at a population level or in a more selective manner from specific health services or laboratories and cases can be reported either syndromically or etiologically based using a laboratory test (Box 6.2). The strengths and weaknesses of these different approaches are compared in Table 6.2.

Many countries have set up special structures for case-reporting.<sup>1</sup> Reporting of cases may either come from doctors or laboratories, or both, and the reporting can be centralized at various levels, depending on the administrative structure of the health service. This system has a natural appeal, in that it can be established on an ongoing basis, provides full geographic coverage, provides information about the presence of the virus in subpopulations, does not appear to involve substantial programmatic expense, and is used for advocacy.<sup>1</sup> The main indicator that can be routinely derived from systems of this kind is the number of new diagnoses over a defined time period. For each case, there is generally an expectation that information will be reported at least on age, sex, and area of residence.<sup>11</sup> This indicator depends very strongly on access to health services and the patterns of testing in a population; it has substantial limitations as an indicator of prevention programs,<sup>1</sup> particularly if it does not provide a denominator to be able to interpret surveillance trends.

### Population-Based Case Reporting

With the advent of tests for HIV antibody in 1984<sup>12</sup> a number of countries adopted HIV case reporting in the latter part of the 1980s.<sup>13–15</sup> In most developed countries, there is now generally a

#### Box 6.2 Examples of Case Reporting Surveillance Systems

- Population-based case reporting
- Selective case reporting
- Syndromic surveillance

**Table 6.2:** Strengths and Weaknesses of Case Reporting

	Population-based case reporting	Selective case reporting	STI syndromic surveillance
Strengths	<ul style="list-style-type: none"> <li>• Straightforward</li> <li>• Ongoing</li> <li>• Full geographic coverage</li> <li>• Provides information about subpopulations</li> <li>• Does not involve substantial programmatic expense</li> <li>• Useful for advocacy</li> <li>• Specific for the infection</li> </ul>	<ul style="list-style-type: none"> <li>• Provides information about populations at high risk of disease</li> <li>• High levels of reporting</li> <li>• Specific for the infection</li> </ul>	<ul style="list-style-type: none"> <li>• Does not require STI testing infrastructure</li> <li>• Cheap</li> </ul>
Weaknesses	<ul style="list-style-type: none"> <li>• Reliant on health seeking behavior and healthcare provider reporting</li> <li>• Suffers from underreporting, particularly in developed countries</li> <li>• May not detect epidemics in specific subpopulations</li> <li>• No testing denominator</li> </ul>	<ul style="list-style-type: none"> <li>• Only a subset of the populations</li> <li>• Reliant on health seeking behavior and healthcare provider reporting</li> <li>• May not detect epidemics in specific subpopulations</li> <li>• No testing denominator</li> </ul>	<ul style="list-style-type: none"> <li>• Nonspecific</li> <li>• Difficult to distinguish current from recurrent infections for some STIs</li> <li>• Poor sensitivity</li> <li>• No testing denominator</li> </ul>

high level of standardization in procedures used for HIV and STI case-reporting, as well as good levels of reporting.<sup>16,17</sup> However, several of the larger countries in Europe, notably Italy and Spain, still do not have national reporting of HIV diagnoses<sup>13</sup> and in the United States, a number of key states have taken some time to adopt HIV reporting.<sup>18</sup> Also in many countries, in the developing world, case reporting systems are not well respected, because they are subject to high degrees of underreporting or incomplete reporting.<sup>19</sup>

### Selective Case Reporting

Selective case reporting involves reporting from a sample of healthcare providers, usually thought to provide services for populations at high risk of diseases. For example in Europe, notification of gonorrhea and syphilis infections is mandatory for all physicians in most countries, whereas laboratory reporting or sentinel case reporting is more common for chlamydia.<sup>20</sup> Selective case reporting has a number of limitations. First, in many countries and even local areas considerable variations exist in clinical sites and the populations who use these services, making comparisons difficult between geographical areas.<sup>20</sup> Second, the coverage of the clinics may vary considerably affecting the representativeness of the reported data.<sup>20</sup> Third, some specialized sexual health clinical sites that attract high risk populations may report a higher proportion of gonorrhea and syphilis cases than genital chlamydial infections.<sup>20</sup> Finally, the lack of denominator data precludes the interpretation of time trends, particularly for chlamydia (Table 6.2).

### Syndromic Case Reporting

In the first years of the HIV epidemic, AIDS case reports provided the only basis for surveillance, and continued to do so on a global basis once HIV was discovered, as testing was not widely available, particularly in developing countries. The international monitoring of the global epidemic was based on AIDS case reports in those years, although there was a recognition that

underreporting of AIDS would be substantial in countries that could not systematically offer testing for HIV to people with suspected AIDS.<sup>21,22</sup> Reporting of AIDS case counts in a number of countries with good surveillance systems provided the basis for estimating past levels of HIV infection<sup>23,24</sup> through mathematical back-projection.<sup>25</sup> In developing countries, the syndromic AIDS case definition, that did not require confirmation of HIV status, was endorsed for surveillance purposes.<sup>26</sup> Until the mid 1990s, progression to AIDS was little modified by treatment, and generally resulted in serious illness and contact with the health system. From 1996 onwards, this situation changed, with the major improvements in therapy, such that AIDS no longer represented and irreversible late stage of HIV disease. AIDS-defining illnesses still arose in people who had access to treatment, but were generally recognized as being as consequence of poor adherence. As a result of the improvement in treatment, many countries saw a fall in the numbers of AIDS cases, with up to half now occurring in people presenting with HIV for the first time.<sup>27–29</sup> Such cases of late presentation indicate a failure of access to HIV testing, and should be tracked to inform public health policy.

In most developing countries, STI syndromic case reporting has formed the basis of STI surveillance for many years as STI tests were yet to be introduced and are still not widely used in all countries.<sup>21</sup> The key syndromes monitored are genital ulcer syndrome: nonvesicular and vesicular, urethral discharge syndrome, vaginal discharge syndrome, and lower abdominal pain in women.<sup>21</sup> STI syndromic case reports have important limitations. First, only genital ulcer disease (nonvesicular) usually represents recently acquired sexually transmitted infections, others syndromes such as vesicular ulcers may represent recurrent HSV infections. Second, most syndromes are quite nonspecific. Many other conditions (other than STIs) cause vaginal discharge and abdominal pain in women. Third, reporting is extremely incomplete because of the asymptomatic nature of many STIs.<sup>21</sup> A recent study in China demonstrated that using syndromic diagnosis identified <10% of positive cases compared to laboratory diagnosis.<sup>22</sup>

Some countries also monitor the syndromes associated with STIs. The example of chlamydia-related pelvic inflammatory disease illustrates the difficulties associated with monitoring of STI complications. The extent of morbidity from chlamydia-associated PID in most counties has been poorly assessed. Methods to measure the extent of PID vary considerably and have involved collation of data from primary healthcare clinics, extraction of data from hospital databases, case-control studies, special surveys, cohorts and data linkages studies. However, most of these assessments are not ongoing and would therefore not strictly fit the definition of surveillance. All these methods have strengths and weaknesses. Cohort studies, particularly those with data linkage components, are the most robust study design, but are associated with significant costs. Studies focused only on hospital settings are cheaper and more feasible but might overestimate progression rates as they include more severe cases. For all methods, the signs and symptoms of nature of PID and epididymitis are nonspecific, there are many causes of PID and an etiological role for *C. trachomatis* is not always definitive; a large proportion of women are only mildly symptomatic; and there is no simple and accurate diagnostic test currently available for diagnosis of PID. Laparoscopy is often used as a “gold standard” in PID diagnosis, but it cannot be practically used in primary care settings, where most cases of PID are managed.<sup>23</sup>

For example in Australia, data have been collated over the past 10 years through extraction of chlamydia-related reproductive outcomes from an annual surveys of general practitioners<sup>24</sup> and extraction of admission data from hospitals.<sup>25</sup> In both these assessments, information about previous chlamydia infections is lacking. In other countries, chlamydia-related reproductive outcomes have also been assessed through cohort studies and/or data linkage projects. For example, in Sweden a large retrospective population based cohort study (the Uppsala Women’s Cohort Study) provides estimates on severe reproductive tract complications associated with diagnosed genital chlamydial infection. Outcomes from the cohort are linked with laboratory, hospital, and population register to estimate the cumulative incidence of hospital diagnosed pelvic inflammatory disease, ectopic pregnancy, and infertility.<sup>23</sup>

### Box 6.3 Examples of Repeated Surveys

- Sentinel surveillance
- Regular behavioral surveillance
- Repeated surveys of HIV/STI prevalence

## Repeated Surveys

Recognizing the limitation of routine case-reporting, many countries have conducted surveys to support the planning and evaluation of HIV and STI prevention programs. The key feature of such surveys is that they obtain information on a defined population that would not arise in the course of routine health service delivery. The population involved in HIV-related surveys have generally been defined by either a behavioral characteristic, such as sexual or injecting activity, or a link to a defined setting such as a clinical service or institution that can be used as a site of recruitment to the survey.<sup>26</sup>

A wide variety of methodological approaches have been used for these surveys, including but not limited to sentinel surveillance of women attending antenatal clinics, cross-sectional surveys and population-based household surveys (Box 6.3).<sup>26–28</sup> The strengths and weaknesses of these different approaches are compared in Table 6.3. Specialized sampling methods such as respondent-driven sampling have also been traditionally used to access “hidden” populations.<sup>29,30</sup>

In the 1980s, when these surveys were first implemented, there was strong support in some countries for using so-called “anonymous unlinked” methods, which involved HIV testing of blood samples taken for other purposes without specific consent.<sup>31</sup> This approach was thought to provide more representative estimates of prevalence than would be obtained through consensual surveys,<sup>31</sup> but this has largely been discredited, because it is seen as depriving individuals of test information that could be to their benefit.<sup>31</sup> ANC sentinel surveillance has continued but now involves provision of results to patients. However, it has a few limitations; only pregnant women are tested, the reason for presentation (pregnancy) can be affected HIV infection, the patient profile may change over time, and the selected sites selected for surveillance may not be representative of the wider community.<sup>32</sup>

**Table 6.3:** Strengths and Weaknesses of Repeated Surveys

	ANC sentinel surveillance	Cross-sectional study	Population based household surveys
Strengths	<ul style="list-style-type: none"> <li>• Convenience sample</li> </ul>	<ul style="list-style-type: none"> <li>• Rich data source</li> <li>• Access to populations that may not attend health service</li> </ul>	<ul style="list-style-type: none"> <li>• Rich data source</li> <li>• Access to populations that may not attend health service</li> </ul>
Weaknesses	<ul style="list-style-type: none"> <li>• Deprives individuals of test information (anonymous unlinked systems only).</li> <li>• Often includes pregnant women only</li> <li>• Pregnancy rates are affected by HIV infection</li> <li>• Limited demographic and behavioral characteristics</li> <li>• Services may not be geographically representative</li> </ul>	<ul style="list-style-type: none"> <li>• Selection bias</li> <li>• Participation bias</li> <li>• May not be repeatable</li> <li>• Some methods are resource intensive</li> </ul>	<ul style="list-style-type: none"> <li>• Participation bias</li> <li>• Suited for generalized epidemics</li> <li>• Costly</li> <li>• Cannot track intermediate trends</li> </ul>

In recent years, there has been increasing use of household-based surveys that attempt to recruit representative samples of the population, especially in settings where HIV infection is believed to be generalized, with predominantly heterosexual transmission.<sup>28</sup> For some years there was a clear distinction between surveys that aimed to collect information primarily on HIV prevalence, either via blood or saliva specimens, and those that sought only behavioral or attitudinal information, but more recently there has been a trend towards integrating the two as far as possible.<sup>26,28</sup>

The integration of HIV testing into household-based surveys has provided greater information on the behavioral risk factors and the demographic and geographical patterns of HIV infection and has allowed ANC surveillance results to be calibrated.<sup>28</sup> On the other hand, the surveys are very costly and resource intensive and therefore only conducted about every 5 years, precluding the ability to track intermediate term trends.<sup>28</sup> Furthermore, participation can be an issue with major differences in the absence and refusal rates between women and men, between urban and rural areas, and between geographical.<sup>28</sup>

## Clinic-Based Surveillance

A key element of the response to the HIV epidemic in many countries has been the provision of HIV and STI testing through various clinical sites, either via pre-existing facilities such as sexual health clinics (Box 6.4), through the establishment of services specifically for the purpose of HIV counseling and testing.<sup>26,33</sup> These sites are often designed in ways that allow them to provide access to particular population groups who may otherwise be marginalized or stigmatized and therefore not attend mainstream health services.<sup>26,33</sup> The strengths and weaknesses of this approach is described in Table 6.4.

Clinical sites that provide HIV and STI testing therefore have the potential to report on several key indicators that may be of interest in program planning and evaluation.<sup>34</sup> The availability of denominator data is particularly useful, because it allows the number of positive HIV or STI tests to be interpreted in the light of testing patterns, providing a positivity rate that can be used as an indicator of the long-term outcome of prevention programs.

Routine testing data collated from clinical sites for the purposes of HIV monitoring and surveillance have been used in both generalized<sup>35–46</sup> and concentrated/low-level epidemics<sup>47–62</sup> for over 20 years. A recent paper by Baryarama et al., actually found that the HIV prevalence among asymptomatic clients

**Table 6.4:** Strengths and Weaknesses of Clinic-Based Surveillance Based on Routine Testing Data

	Clinic-based HIV/STI surveillance based on routine clinical data
Strengths	<ul style="list-style-type: none"> <li>• Rapid results</li> <li>• Minimal burden to sites</li> <li>• Access to high-risk groups</li> <li>• Can provide information on routinely collected risk behavior</li> <li>• Can be a proxy for prevalence if high testing rates</li> </ul>
Weaknesses	<ul style="list-style-type: none"> <li>• Select bias</li> <li>• People with established HIV infection will attend for HIV testing, so not a true reflection of prevalence (more a reflection of diagnosis rate)</li> <li>• May not be generalizable to wider population</li> </ul>

attending 8 standalone VCT sites across Uganda was similar to that in national HIV serosurvey data overall (10.1% and 9.7%, respectively).<sup>46</sup> However, in countries with high rates of testing and detection of infection, the positivity rates may not be a true reflection of prevalence but more an indicator of the rate of new diagnosis.<sup>46</sup> For example, in Australian diagnosis rates obtained from a clinic-based surveillance systems in Victoria have been reported at around 2% for men who have sex with men in the last few years,<sup>63</sup> whereas a recent prevalence study suggests the prevalence may be closer to 13%.<sup>64</sup>

In regards to STIs, surveillance systems based on routine testing data are being rolled out increasingly and proving useful in the interpretation of chlamydia passive surveillance trends. In the year 2000, a comprehensive surveillance system (called ASSIST) was introduced in the UK, which collates individual-level data about all laboratory tests for sexually transmitted infections carried routinely out in departments of GUM, the Avon Brook clinic, and the Health Protection Agency and trust laboratories.<sup>65</sup> The system demonstrated there was an increasing number of chlamydia positive tests being reported, which could be interpreted as being due to increased transmission; however chlamydia positivity rates in the area did not increase.<sup>65</sup>

On the other hand, in Australia, there was an increasing number of case reports of chlamydial infections notified; however chlamydia positivity rates in young heterosexual women aged less than 25 years, reported through the sexual health service network showed a significant increase between 2004 and 2008, from 10%–13%. These data from Australia suggest the rise in case reports may be related to increased transmission in the community.<sup>66</sup>

In clinical sites, where testing rates are high, the STI positivity rate may be reliably used a prevalence measure among the people attending the service.<sup>67</sup> Clinical sites are also in a position to provide information on risk behavior that is routinely obtained from clients<sup>33</sup> and can serve as an outcome indicator for prevention programs. The routine nature of the data also allow for rapid epidemiological assessment of populations affected and changes in the burden of disease.

### Box 6.4 Examples of Clinic-Based Surveillance Systems

- Screening for syphilis in antenatal women
- Testing of blood donors for HIV
- Examination for STIs among sex workers attending a special clinic
- Reports of risk behavior among students attending tertiary health services

The main methodological disadvantage of using indicators collected from routine practice at clinical sites is that they may be unrepresentative of populations in whom the program implementation is taking place.<sup>26</sup> Also unless there is a large network of services that cover the populations at risk, then there is the possibility of the system also being unrepresentative. For example, the paper by Baryarama et al. found that the VCT estimates were higher among rural VCT clients compared to rural serosurvey participants (8.2% and 5.2%, respectively) and the authors suggested the findings reflect of self-selection bias among rural VCT clients.<sup>46</sup> On the other hand, a number of populations of importance for HIV prevention cannot be reliably accessed in any other way,<sup>31</sup> and there is no reason to assume that indicators derived from routine clinical practice will be any less representative than those that are obtained by other means.

### MEASURING HIV INCIDENCE THROUGH SURVEILLANCE SYSTEMS

The central objective of HIV and STI prevention programs is to reduce the extent of transmission accordingly. Incident HIV infection rates are a key programmatic indicator as they reflect the rate of transmission<sup>68</sup> and help determine both the need for intervention programs and their effectiveness, but are very difficult to measure in practice. Direct measurement of incidence requires the use of repeat HIV/STI testing in the setting of cohort studies, which are not generally incorporated into routine surveillance systems as they are too expensive to be undertaken as ongoing population monitoring initiatives.<sup>68</sup> Prospective cohort studies are also complex, require long and costly follow-up and data are also subject to biases such as the Hawthorne effect.<sup>69</sup> Given the importance of HIV/STI incidence as an indicator, a number of alternative approaches have been used to provide HIV incidence estimates including repeat testing, specialized HIV serological assays and mathematical techniques

#### Box 6.5 Examples of Systems to Measure HIV/STI Incidence

- Repeat testing in a cohort
- Repeat testing in a clinical setting
- Prevalence of HIV infection in people whose first episode of drug injecting has been within the past year
- Specialized serological assays
- Mathematical techniques

(Box 6.5). The strengths and weaknesses of these different approaches are compared in Table 6.5.

The use of repeat-testing data is appealing for estimating HIV incidence for several reasons; it includes large sample sizes, demographic characteristics and risk behavior data are routinely recorded, includes high risk population, who may otherwise not participate in cohorts or other research.<sup>69</sup> However, the method has some weaknesses selection bias due to changes in the client profile or testing patterns over time and people may seek testing and treatment for infections outside the clinic that is being monitored.

The findings from prevalence surveys can be used to provide indirect estimates of incidence in people whose earliest exposure to HIV/STI infection can be assumed to have been relatively recent. For example, the prevalence of HIV infection in people whose first episode of drug injecting has been within the past year can be taken as a surrogate for 1-year incidence, provided other sources of infection are unlikely.<sup>70</sup> Studies in Africa have assessed trends in HIV incidence by analyzing the results of HIV prevalence among 15–24 year-old pregnant women.<sup>71</sup>

A major technical advance in surveillance over the past decade has been the development of serological assays that can be applied to single specimens to distinguish recently acquired HIV infections from those of longer duration.<sup>72</sup> These tests can be applied to specimens obtained either through routine case-reporting,<sup>73</sup> prevalence surveys,<sup>74</sup> or clinic-based surveillance,<sup>75–77</sup> and used as the basis for estimating incidence. Examples of

**Table 6.5:** Strengths and Weaknesses of Systems that Measure HIV Incidence

	Cohort	Repeat testing in a clinical setting	Serological assays	Mathematical techniques
Strengths	<ul style="list-style-type: none"> <li>• Direct measure</li> </ul>	<ul style="list-style-type: none"> <li>• Cheap</li> <li>• Data are widely available</li> <li>• Large sample sizes</li> <li>• Includes high risk f people</li> <li>• Long time periods</li> </ul>	<ul style="list-style-type: none"> <li>• Can be applied to a single specimen collected in a cross-sectional study</li> </ul>	<ul style="list-style-type: none"> <li>• Cheap</li> <li>• Calculation based on data from other studies</li> </ul>
Weaknesses	<ul style="list-style-type: none"> <li>• Expensive</li> <li>• Complex</li> <li>• Long follow-up</li> <li>• Differential loss to follow-up</li> <li>• Hawthorne effect</li> </ul>	<ul style="list-style-type: none"> <li>• Indirect measure</li> <li>• Reliant of frequent testing behavior</li> <li>• Results require continual revision with subsequent years of data</li> </ul>	<ul style="list-style-type: none"> <li>• Indirect measure</li> <li>• Cross sectional sample–selection bias</li> <li>• Can misclassify AIDS cases and people in ARV treatment</li> <li>• Involves complex mathematical calculations</li> <li>• Requires an appropriate definition of the population the incidence is estimated for</li> </ul>	<ul style="list-style-type: none"> <li>• Indirect measure</li> <li>• More accurate in the early years of the HIV/AIDS epidemic</li> </ul>

the public health application of these assays have been studies involving attendees at anonymous testing clinics,<sup>69,77</sup> sexually transmitted disease clinics,<sup>75–77</sup> and injecting drug users attending treatment services.<sup>78–80</sup>

A number of public health agencies are already using these tests on a routine basis. Currently, HIV incidence assays have been incorporated into national HIV incidence surveillance in the USA<sup>81</sup> and increasingly in Europe. In Africa, 15 of 44 sub-Saharan African countries report HIV incidence estimates and HIV incidence assays have comprised 20% of these estimates since 2006.<sup>82</sup>

Despite this, there is not yet a consensus on their ideal means of application, and particular debates about the validity of the resulting estimates of HIV incidence.<sup>74,83</sup> Guidelines are currently being prepared by the World Health Organization that contains advice on the recommended validation strategies and ideal ways to use the assays in routine surveillance.

## Surveillance for Drug Resistance

Given the importance of providing the correct treatment for STIs and HIV, many countries have implemented gonococcal antimicrobial resistance surveillance programs; some systems have been in place for 10–20 years. More recently a number of countries have introduced HIV drug resistance surveillance (Box 6.6). The strengths and weaknesses of these different approaches are compared in Table 6.6.

## HIV Resistance Surveillance

Surveillance for transmitted drug resistance has become a routine HIV surveillance activity in a number of countries including France, Canada, Australia, and others.<sup>66,84,85</sup> At the population level, information about the occurrence of transmitted drug resistance and its time trends and distribution in the population, can guide overall treatment policy, particularly in regard to

preferred first line therapeutic options. In some regions of the world, if the proportion of resistance in this population reaches a specified level (e.g., 5% or 10%), routine drug resistance testing may be recommended for all persons known or assumed to be recently infected with HIV who are newly diagnosed or who are beginning HIV treatment.<sup>84</sup>

The World Health recommends that the surveillance of drug resistance in newly diagnosed persons with HIV should not be initiated until there is an indication that the level of transmitted resistance in the country may be at or above 5%, but planning should take place before that point, including threshold resistance surveys. WHO recommends that if the surveys detect HIV strains containing major mutations associated with resistance in 2 successive years, then surveillance should be considered. The threshold surveys can also provide the opportunity for testing methodology and evaluating potential sentinel surveillance sites.<sup>84</sup>

The surveillance systems can focus on all new diagnosis or only those that are identified as recently acquired. Each of these approaches have strengths and weaknesses. Annual monitoring of target groups representative of persons recently infected with HIV provides the best estimate of trends in drug resistant HIV transmission. Specimens from the recently infected provide important information about the transmission of mutations associated with new drugs and provide a direct estimate of the incidence of transmitted resistance. This is the current situation in Australia, where HIV surveillance captures a person's past testing history enabling newly acquired infections to be easily identified and account for about 30% of diagnoses.<sup>85</sup> However, this approach is not usually practical in resource-limited countries. Newly infected individuals are often difficult to identify in many countries; the majority of individuals with HIV are not diagnosed until late in their clinical course, when disease develops.<sup>84</sup>

HIV drug resistance surveillance focused on newly diagnosed HIV infections is more commonly conducted as such populations are generally accessible. Newly diagnosed HIV infections generally represent new patients likely to be evaluated for treatment by a clinician and can provide helpful information about mutations that remain detectable years after infections. By focusing on newly diagnosed infections the prevalence of HIV drug resistance prevalence is unlikely to relate to a certain time period but the

### Box 6.6 Examples of Systems to Measure HIV and STI Drug Resistance

- HIV antiretroviral therapy resistance surveillance
- Gonorrhea antimicrobial resistance surveillance

**Table 6.6:** Strengths and Weaknesses of Drug Resistance Surveillance

	HIV drug resistance surveillance—newly acquired infections	HIV drug resistance surveillance—new diagnoses	Gonorrhea antimicrobial resistance surveillance
Strengths	<ul style="list-style-type: none"> <li>• Best indicator of whether mutations associated with new drugs is being transmitted</li> <li>• Enables trends to be assessed over time</li> </ul>	<ul style="list-style-type: none"> <li>• More accessible populations</li> <li>• The total numbers of newly diagnosed individuals are often known</li> </ul>	<ul style="list-style-type: none"> <li>• Most countries with laboratory infrastructure can undertake AMR surveillance</li> </ul>
Weaknesses	<ul style="list-style-type: none"> <li>• Newly infected individuals are often difficult to identify in many countries</li> </ul>	<ul style="list-style-type: none"> <li>• Does not reflect transmitted resistance within a certain time period</li> <li>• Proportions of recently infected persons may change from year to year that could affect trends</li> </ul>	<ul style="list-style-type: none"> <li>• Sensitivity</li> <li>• Representativeness</li> </ul>

incidence of transmitted resistance can be estimated from the subset of recently infected persons in the population. The main limitation of monitoring newly diagnosed infections is that over time there could be changes in the proportions of recently and established infections in the sample, which could bias trends in resistance.<sup>84</sup>

### Gonorrhea Antimicrobial Resistance (AMR)

AMR surveillance is crucial to inform treatment options as it is well established that once resistance to an antibiotic has reached a level of 5% or more, the antibiotic should be removed from treatment schedules for gonorrhea infection.<sup>85</sup> Unlike other bacterial STIs, *Neisseria gonorrhoeae* has a particular capacity to become resistant to antibiotics leading to the removal of penicillins, tetracyclines, and now quinolones from the treatment schedule in many countries.<sup>85</sup>

Surveillance for AMR is common in many countries including Australia, the United Kingdom (UK), United States (US), Sweden, South Africa, and recently Russia.<sup>85</sup> There are also regional programs including the WHO WPR and South-East Asia Regions (SEAR), Gonococcal Surveillance Programmes (GASP) and a program in the European Union. However in many countries and regions AMR surveillance is absent such as in Canada, Malaysia, America, and Africa.<sup>85</sup>

The surveillance methods employed across countries vary. For example in the UK, isolates collected from patients attending sentinel sites over a 3-month period are assessed. Whereas in the US, the program involves assessment of specimens from male patients in 25 sentinel sites each month. Further to this, in Australia, the US, and the UK, MIC-based methods are used to assess resistance, whereas the WPR GASP uses a number of methods including disk diffusion.<sup>85</sup>

Similar to issues faced by other sentinel surveillance programs, AMR often suffers from representativeness issues as in many countries it is difficult to define an appropriate sentinel population that can provide sufficient samples to present all populations at risk of gonorrhea.<sup>86</sup>

### Choice of Surveillance Systems

Given the variety of options for surveillance, all with individual strengths and weaknesses, it is perhaps unsurprising that virtually all countries, and to some extent different jurisdictions within countries, have come up with their own combinations of methods to measure key indicators of HIV prevention initiatives.<sup>87</sup> Surveillance systems are never perfect and vary considerably according to the area of public health being monitored, the available resources, and factors such as the structure of the health system in which it is operating and sociocultural factors. Furthermore, it is difficult to assert in any absolute sense that one system or set of systems is clearly superior to another.

Nevertheless, there are some criteria that have emerged for guiding the choice of system. Governments and their partners in HIV prevention take these criteria into consideration in determining ideal strategies for the populations that fall under

their responsibility. At a practical level, the surveillance system must fit within the budget and structure of the overall health system at any given time. There is no point in countries designing systems that are not properly resourced, nor should they try to put in place surveillance mechanisms that create tensions with service provision. Similarly, there may be political or cultural constraints that have an impact on the methodological options available for surveillance systems.

From a scientific and public health perspective, it is clear that HIV epidemics can differ considerably over place and time, and the monitoring systems that are used to guide prevention initiatives need to reflect the current state of the epidemic in a given setting.<sup>1</sup> In any country experiencing an HIV/AIDS epidemic, the relationship between prevalence and incidence, and the behavioral and demographic profiles of already-infected versus at-risk individuals, changes over time as the epidemic becomes more established in the population. The ongoing challenge for surveillance systems, whether they are related to HIV infection or any other condition, is to be sufficiently stable to allow valid comparisons to be made over time, at the same time as being responsive and adaptable to an evolving environment, should the patterns of infection start to qualitatively change.<sup>1</sup>

#### Summary

The most widely used surveillance mechanism for monitoring HIV/STIs is based on the routine reporting of newly diagnosed cases to a central public health unit. Selective case reporting also occurs in some countries and involves reporting from a sample of healthcare facilities providing services for populations at high risk of diseases. In most developing countries, STI syndromic case reporting has formed the basis of STI surveillance for many years as STI tests were yet to be introduced and are still not widely used in all countries. Recognizing the limitation of routine case-reporting, many countries have conducted behavioral and biological surveys to support the planning and evaluation of HIV and STI prevention programs. A wide variety of methodological approaches have been used for these surveys, including sentinel surveillance of women attending antenatal clinics, cross-sectional surveys, and population-based households surveys. A number of approaches have been used to provide HIV incidence estimates including repeat testing, specialized HIV serological assays, and mathematical techniques. Surveillance for HIV drug resistance and gonorrhoea antimicrobial resistance has become a routine surveillance activity in many countries. The chapter discusses strengths and weaknesses of all these systems, and criteria for guiding the choice of system in a country.

# Epidemiological Interactions between HIV-1 and other STI: A Complex, Continuing Narrative

# 7

Brian P. Mulhall

## Early Studies

Not long after the first published description of AIDS<sup>1</sup> and the discovery of its cause, the human immunodeficiency virus (HIV),<sup>2,3</sup> studies in men who have sex with men (MSM)\* suggested an association with sexual behavior and STI,<sup>4-12</sup> but deficiencies in study design<sup>13</sup> hampered definite conclusions. For the next 15 years or so, little further research was undertaken in MSM regarding associations with STI; resources were instead directed toward effective treatments of HIV-infected individuals with antiretroviral drugs (ARV). In the last decade, there has been a resurgence of interest in studies of homosexual/MSM that have concentrated instead on the effect that STI have on the infectiousness of HIV-infected MSM. These will be reviewed later in this chapter.

From similar beginnings, reports from Africa and elsewhere showed that HIV was also transmitted during heterosexual intercourse, overshadowing the MSM epidemic; additionally, cross-sectional studies<sup>14-16</sup> suggested that genital ulcer disease (GUD) facilitated transmission of HIV. The evidence was stronger in those studies that were prospective,<sup>17-19</sup> with odds ratios that ranged from 2–4 times for GUD, and less for non-GUD.

In 1991, a landmark paper by Judith Wasserheit,<sup>20</sup> examining the potential interrelationships between HIV and other STI, coined a new concept, “epidemiological synergy”, by which was meant that each infection could amplify the other. Three mechanisms were suggested:

1. Increased transmission of HIV in the presence of other STI
2. Accelerated progression of HIV disease in the presence of STI
3. Alteration in the natural history, diagnosis, or response to therapy of other STI in the presence of HIV infection.

The last proposition is dealt with in Chapter 84 by Veerakathy Harindra, and the second will be reviewed only briefly owing to

paucity of evidence; therefore, the majority of this chapter will deal with the first proposition.<sup>1</sup>

In theory, increased transmission could occur as a result of:

- (a) Increased acquisition of HIV in the presence of STI, perhaps by disruption of mucosal integrity, or by a concentration of inflammatory cells in the presence of STI, some of which would be permissive for HIV infection, or
- (b) Increased shedding of HIV in genital secretions, due to an increased viral load in the presence of infection, in this instance by another STI.

## Establishing Epidemiological Synergy

Despite a number of studies suggesting an association, there were obstacles to establishing a causal role for STI. The most obvious was the confounding variable of sexual behavior, which was associated with the exposure variable (STI) as well as the outcome of interest (HIV). In addition, any sample of persons studied might not provide true information about the relationship between exposure and outcome with respect either to the relationship that the sample actually displayed (selection bias), or apparently displayed (classification bias). In practice, epidemiologists attempt to do sufficient studies in diverse settings, thus limiting random error, systematic error (bias), and logical error (confounding).

In assessing the causal nature of an observed association, the Bradford Hill “criteria”, (he called them “considerations”), first published 45 years ago,<sup>21-23</sup> have long provided a background framework, akin to Koch’s postulates (Fig. 7.1 and Box 7.1).

In practice, it is difficult to establish a pure association of exposure (STI) and health outcome (HIV)-free from bias, confounding, and interaction with other exposures. The research situations in which this can occur are limited mainly to clinical trials, and perhaps large observational studies with impeccable design and execution. In the present context, epidemiologists

\*MSM (men who have sex with men) is a term that includes all men with significant same-sex sexual behaviors; it includes men who self-identify as homosexual, gay, or bisexual, as well as those who do not. The early studies referred to here were mainly in the former group.

**Fig. 7.1:** Sir Austin Bradford Hill (right), the father of medical statistics, seen here with Sir Richard Doll in 1950; in background their article on smoking.

#### Box 7.1 Bradford Hill Criteria for Causality

- Strength
- Consistency
- Specificity
- Temporality
- The only requirement, that is, for the exposure (STI) to precede the effect (HIV)
- Biological gradient
- Biologic plausibility
- Coherence
- Analogy
- Experiment

The strongest evidence for causality. Do preventative actions taken on the basis of a demonstrated cause and effect association alter the frequency of the outcome?

extended their horizons to encompass the domains of population-level relationships not reducible to studies of individuals. It should, however, be noted that neither observational nor treatment studies are able to easily separate the effects of STI on the infectiousness of HIV from their effects on HIV acquisition.

### Randomized Controlled Trials of STI to Prevent HIV

There have been six randomized controlled trials (RCTs) for bacterial STI, all in Africa,<sup>24,28–32</sup> and two for herpes genitalis.<sup>105,106</sup>

Results for the first three have been subjected to intense scrutiny for over 10 years. All used communities, rather than individuals, as the unit of randomization; for the first three, considered prototypes, the protocols can be summarized as follows in Box 7.2.

The results from Mwanza were published first<sup>24</sup> and showed a remarkable reduction in HIV incidence of 48% (Estimated RR 0.58, 95% CI 0.42–0.79,  $p = 0.007$ ).

It is easy, in retrospect, to understand the jubilation that accompanied this news in the scientific literature,<sup>25,26</sup> including

#### Box 7.2 Protocols and Results on HIV Incidence for the First 3 Intervention Trials in Africa

- A. Mwanza, Tanzania, 1991–1995. Intervention—improved STI treatment protocols via syndromic management in 6 communities, versus delayed intervention in 6 matched communities, total  $n = 12,537$  individuals.  
48% reduction in HIV (RR 0.58, 95% CI 0.42–0.79)
- B. Rakai, Uganda, 1994–1998. Intervention—mass STD treatment at 10-monthly intervals, versus placebo (vitamins and antihelminthic treatment). Ten community clusters, randomized, total  $n = 12,726$  individuals.  
No effect on HIV (RR 0.97, 95% CI 0.81–1.16)
- C. Masaka, Uganda, 1995–2001. Three intervention arms—behavioral (A), syndromic treatment (B), and routine community development activities (C). 18 rural communities were chosen, with a total population of about 96,000. No effect on HIV. The incidence rate ratios were (A) 0.94 (95% CI 0.60–1.45), (B) 1.24 (95% CI 1.02–1.56), (C) 1.0

the claim that Bradford Hill's criteria for causality had now been definitively established; however, this was only on the basis of the Mwanza experiment.<sup>27</sup>

It was some time before the Rakai and Masaka results were available, and to general dismay, neither showed any effect on HIV incidence.<sup>28,29</sup>

In Rakai incidence of HIV was 1.5 per 100 person years in both arms (RR 0.97, 0.81–1.16), with a significant decrease only in syphilis (RR 0.80, 0.71–0.89), and trichomoniasis (RR 0.59, 0.38–0.91).

In Masaka, there were no significant differences on any measure between the three arms.

The fourth trial, again flat (null) for HIV,<sup>30</sup> will be discussed in the section on periodic presumptive treatment (PPT); the last two, both null<sup>31,32</sup> have not been the subject of significant comment or debate in the literature.

In contrast, a large number of papers have been published over an extended period of time, reflecting the degree of concern over the perplexing, contrasting, and seemingly contradictory results of the three prototype trials.<sup>33–40</sup> Some of the explanations advanced are listed in the Box 7.3.

In the previous section on association and causality, it was stated that research situations free from bias and confounding are rare. They are limited mostly to clinical trials, and we have seen that the trials above were certainly not free from bias or confounding. Another kind of study that attempts to minimize epidemiological noise is a large observational study with impeccable design and execution.

One such study has been conducted in Africa, popularly known as the Four Cities study. The HIV epidemic shows considerable heterogeneity within sub-Saharan Africa. The multicenter study of factors determining the different prevalences of HIV in sub-Saharan Africa was designed to assess whether differences in characteristics of sexual behavior and/or factors affecting the probability of HIV transmission such as male circumcision or STI could explain the much more severe epidemics observed in East Africa than in West Africa. This cross-sectional, population-based study sampled about 1,000 men and 1,000 women in each of 2 cities with relatively low HIV prevalence (Cotonou, Benin; and

Yaounde, Cameroon) and 2 cities with high prevalence (Kisumu, Kenya; and Ndola, Zambia).<sup>41</sup>

The study found that some biological factors for HIV transmission differed between the high and low prevalence cities. In the cities with low prevalence, virtually all the males were circumcised, whereas in the cities with high prevalence, rates of circumcision were low—28% in Kisumu and 10% in Ndola. In addition, the prevalence of herpes type 2 (HSV-2) was higher among young women and men in the East African cities than in the West African cities. The study also identified some important differences in reported sexual behavior between the four populations including younger age at first intercourse and marriage in East Africa than in West Africa and larger age differences between spouses in East Africa. On the other hand, other characteristics of sexual risk behavior such as reported partner change rates and having had sex with a sex worker were more prevalent in the cities with low prevalence than in the cities with high prevalence. Hence, an important hypothesis raised by the study was that differences in risky sexual behavior could be outweighed by differences in biological cofactors that unduly influence HIV transmission, such as male circumcision and other STI, especially HSV-2.<sup>42</sup>

## Systematic Review of Data

In 2001 a systematic review,<sup>43</sup> of the large body of work accumulated thus far measuring the associations between STI and HIV, concluded that (assuming that confounding and publication biases were eliminated successfully) GUDs increase male susceptibility approximately 4 times, and female susceptibility 3 times, whereas non-GUD increase male susceptibility 3 times and female susceptibility 2 times. There also appeared to be a 2 times increase in the infectiousness of HIV sources with an STD, although data were very sparse for women with a non-GUD.

## Syndromic Treatment, Mass Treatment, Core-Theory, and Periodic Presumptive Treatment

We have seen that syndromic treatment of STI to reduce HIV was effective in the context of a clinical trial. Elsewhere, however, asymptomatic STI cannot (by definition) be treated within the syndromic paradigm, and together with other operational considerations, reduce its efficacy.<sup>44</sup> Moreover, mass treatment cannot achieve full coverage, and even if it could, would be too costly.

Therefore, a third approach has been trialled; it is currently known as periodic presumptive treatment (PPT), and relies heavily on “core-theory”, an introduction to which is now introduced as essential background information.

Yorke and colleagues studied the effects of a 1972 screening program for gonorrhea in asymptomatic women in the USA,<sup>45</sup> trying different models against seasonal oscillations of positive results. They showed that the “infecter number”—the average number of susceptible persons infected per infected index case during his or her infectious period—must exceed one for the

### Box 7.3 Possible Reasons to Explain Discrepancies between the First 3 Trials in Africa

- Curable STI may play a more important role in an early HIV epidemic (Mwanza, HIV prevalence 6%), versus a mature HIV epidemic (Rakai, HIV prevalence 16%)
- Suboptimal measurement of STI in Mwanza
- Suboptimal coverage in Rakai, including the possibility of reinfections
- Symptomatic STI (Mwanza) may be greater cofactors than asymptomatic STI (Rakai)
- There were lower rates of curable STI in Rakai, owing to lower risk behaviors
- The population attributable fraction (PAF) of STI to HIV may differ between populations
- The near impossibility of fully resolving the spurious effect of confounding sexual behaviors, particularly in the unknown partners of study participants

disease to be at an endemic equilibrium. The infected population would be closed by a saturation effect if there was acquired immunity, or by a pre-emption effect (already infected) if there was no such immunity (as in gonorrhea). Groups having a high prevalence, e.g. 20%, had substantial pre-emption effects, and formed a reservoir, or core-group.

In 1987–1988, only a few years after AIDS was first described, Robert May and Roy Anderson, using remarkably prescient estimates of the incubation period for AIDS, among other assumptions, brilliantly developed a simple model to describe the infector number, or “reproductive rate” for HIV, and indeed, most infectious agents, including STI.<sup>46,47</sup> Essentially, they showed that the potential for spread within a specific risk group depends on the magnitude of the basic reproductive rate ( $R_0$ ).  $R_0$  measures the number of infections produced, on average, by an infected individual in the early stages of an epidemic, when virtually all contacts are susceptible. As such, it depends on the average probability,  $\beta$ , that an infected individual will infect a susceptible partner, times the rate of partner change,  $c$  (within the specified risk category), times the average duration of infectiousness,  $D$ ; thus  $R_0 = \beta c x D$ .  $R_0$  must  $>1$  for an infection to be sustained, and to be an ecologic success.

Discussing this further, Brunham and Plummer<sup>48</sup> add that great heterogeneity in sexual behavior exists at the population level, with only a subset maintaining high rates of partner change. When rates of partner change per unit time are plotted from a random sample of an entire population, the distribution is nonnormal<sup>49</sup> (Fig. 7.2). A long tail of individuals who have high rates of new partner acquisition is observed. These individuals who have a high prevalence and incidence of STI, act as a reservoir of infection, and are the source of infection to others. They are termed core-groups, or high transmitters of STI.

**Fig. 7.2:** When rates of partner change per unit time are plotted from a random sample of an entire population, a long tail of individuals who have high rates of new partner acquisition is observed.<sup>49</sup>

The core-group concept has immediate and profound implications for STI control. If core-group members are kept free of infection, STI will gradually disappear.<sup>50</sup>

Thus, the concept of epidemiologic/targeted mass treatment of core-groups was developed,<sup>51</sup> and then tested in a group of female sex worker (FSW) and their clients in 1996–1997 in a mining town in South Africa.<sup>52</sup> High-risk women attended a clinic monthly, and were treated presumptively with a directly observed dose of 1g azithromycin. During the first 9 months of the intervention, the prevalence of gonorrhea and/or chlamydia fell from 24.9% to 12.3% within the first month; there was also a decline in GUD from 9.7% to 4.4%. In the client population (miners), the analogous figures were 10.9% and 6.2% at 6 months, and 5.8% to 1.3% for GUD.

A similar intervention was instituted for FSWs in a slum area of Nairobi between 1998 and 2002, using monthly azithromycin.<sup>53</sup> This was additionally, an RCT for HIV prevention (the fourth in Africa); 466 HIV-negative FSWs were randomly assigned to drug or placebo, the primary study end-point was incidence of HIV. The results at 2 years showed a significant reduction in gonorrhea (RR 0.46, 95% CI 0.31–0.68) and Chlamydia (RR 0.38, 95% CI 0.26–0.57), but not in HIV (RR 1.2, 95% CI 0.6–2.5). The authors suggested that prevalent HSV-2 infection may have been an important cofactor; however, others have pointed out that the prevalence of HIV and GUD (especially chancroid) had already fallen to low levels in this population.<sup>54</sup> A very interesting finding in this study was the strong association between HIV incidence and a recently acquired STI, raising the possibility that STI may facilitate HIV transmission via increased infectivity of a coinfecting partner.

There followed other documented successes of PPT in various other populations and under differing operational circumstances,<sup>55–57</sup> and in September 2005, WHO convened a meeting in London to consider experiences with PPT, and to issue recommendations.<sup>58</sup>

The principal determinants of success for PPT depend on individual circumstances that include a high proportion of curative STI, and how closely these are linked to core-groups, e.g. FSWs. They should probably be best considered as a temporary intervention to rapidly reduce rates of STI in populations with limited access to health services. Treatment of the FSWs regular sexual partners is also important. They are not a magic bullet, and operational issues remain, including optimal frequencies, anxieties regarding antibiotic resistance to gonorrhea, cost, and possible disincentives to condom use. Nevertheless, they have been used successfully in many different populations (Fig. 7.3). Their contribution to HIV prevention remains unknown.

## Influence of Stage of HIV and Other STI on HIV Viral Load

The application of the polymerase chain reaction (PCR) (Fig. 7.4) to HIV in plasma and other body fluids shed new light on the dynamics of HIV and enabled the number of viral particles (“viral load”) to be determined at any stage of HIV-1 infection.<sup>59–64</sup>

**Fig. 7.3:** Impact of PPT on GC and CT among female sex workers in Asia and Pacific, 2002–2009. *Source:* Bruce E, Australasian Sexual Health Conference 2008; McCormick D, FHI 2007; CHAS Lao PDR 2008; Bollen LJM et al., *Sex Transm Infect* 2010;86:61–5; and Graham Neilsen, FHI 2010 (reproduced with permission).

**Fig. 7.4:** Advances in Technology. Polymerase chain reaction.

**Fig. 7.5:** Median concentration of HIV-1 in semen among 135 HIV-infected men in Malawi with and without urethritis.<sup>68</sup> Cohen et al. *Lancet* 1997;349:1868–73 (reproduced with permission).

Preliminary studies in Nairobi and elsewhere<sup>65,66</sup> demonstrated fluctuations of HIV in semen associated with urethritis. In Malawi, using a new assay,<sup>67</sup> Cohen and colleagues demonstrated in 1997<sup>68</sup> that HIV-shedding in semen was 8 times greater in HIV-positive men with urethritis ( $12.4 \times 10^4$  copies/ml) than in a control group of HIV-positive men without urethritis ( $1.54 \times 10^4$  copies/ml), despite similar CD4 counts and plasma viral loads. Gonorrhea was associated with the greatest concentration of HIV. Moreover, after the urethritis patients received antimicrobial therapy, the concentration of HIV in semen decreased to  $8.91 \times 10^4$ /ml at 1 week and  $4.12 \times 10^4$ /ml at 2 weeks (Fig. 7.5). The concentrations in plasma were unchanged. These were important observations because during sexual transmission of HIV, the relevant secretion is likely to be semen or cervical fluid, with blood levels a surrogate marker.

Nonetheless, a landmark study in 2000 demonstrated that plasma viral load was the chief predictor of heterosexual transmission of HIV<sup>69</sup> (Fig. 7.6).

The Rakai trial data<sup>28</sup> identified 415 couples in which one partner was HIV-positive, and one was initially negative; 90 of

**Fig. 7.6:** Viral load and HIV-1 transmission.<sup>69</sup> Quinn TC et al., *N Engl J Med* 2000;342:921–9 (reproduced with permission).

the 415 initially HIV-negative partners seroconverted. The rate of male-to-female transmission was not significantly different from the rate of female-to-male transmission. The mean serum HIV RNA level was significantly higher among HIV-positive subjects whose partners seroconverted than among those whose partners did not seroconvert. There were no instances of transmission among the 51 subjects with serum RNA less than 1,500 copies/ml. They found a dose-response effect; the rate of transmission increased from 2.2 per 100 person-years to 23.0 per 100 person-years as the serum HIV RNA level increased from less than 3,500 copies/ml. Each log increase in viral load was associated with an increase, by a factor of 2.45, in the risk of transmission. Apart from previous studies on mother-to-child transmission this was the first (and remains the best) study of heterosexual risk of transmission. In a subsequent analysis of the same cohort,<sup>70</sup> 174 monogamous couples were identified, and the probability of transmission per coital act estimated from frequency of sexual intercourse. The probability of transmission increased from 0.0001 with a plasma viral load <1700 copies/ml to 0.0023 at >38000/ml; in addition, there was a significant increase at all viral loads if there was a history of genital ulceration (0.0041 vs 0.0011,  $p = 0.02$ ) (Fig. 7.7).

Meanwhile, in Malawi, Cohen's group showed, for the first time, that during "acute HIV" infection (best described as the period between infection with HIV and the appearance of antibodies routinely used to diagnose infection), the peak serum HIV load was extremely high, often >1 million copies/ml.<sup>71,72</sup> At the clinic level, therefore, patients could be given negative antibody results, yet still be very infectious "super-shedders". The same group, using new assays to improve HIV detection in semen,<sup>73</sup> developed this concept considerably<sup>74,75</sup> to infer different infectivities at different stages of HIV-infection. By measuring HIV concentration in blood and semen samples from patients with acute and long-term infection, they observed that semen concentrations increase and decrease in approximate parallel with changes occurring in blood. Their models suggest that

**Fig. 7.7:** Probability of HIV transmission per coital act in monogamous, heterosexual, HIV-discordant couples in Rakai, Uganda<sup>70</sup> (reproduced with permission).

**Fig. 7.8:** The effects of intermittent STI on the probability of sexual transmission of HIV<sup>76</sup> (reproduced with permission).

acute dynamics alone are sufficient to increase probability of HIV-transmission by 8–20 times between peak levels, termed “ramped-up viremia” (day 20 after infection), and the virological “set-point” (day 54 and after).<sup>76</sup> During a long asymptomatic phase, the viral load would remain low, except during episodes of classic STI when there would be “break-through” increases in viral load in semen (Fig. 7.8). It should be emphasized that suppression of HIV in the genital tract by ARV is incomplete. Sadiq and colleagues reported detection of HIV in semen of subjects suppressed by ARV when they acquired STI; the variants they recovered were resistant to the ARV administered.<sup>77</sup> Given that many people with HIV acquire STI, such “break-through” viral loads could represent a significant risk for HIV transmission. In the last stages of HIV disease, when AIDS develops, the viral load would rise again, together with infectiousness, if the individual was still sexually active. To a considerable extent, this model of infectivity has dominated concepts of HIV infectiousness by stage of HIV infection, and the influence of other STI.

The same group also showed (using a pooling serum strategy to minimize costs) that antibody-negative sera could be screened for viral RNA. For example, 100,000 serum samples for blood donation were examined in “real time” over 12 months in North Carolina.<sup>78</sup> Twenty three positive subjects were identified; most, unsurprisingly, were found in STI clinics.

In a further analysis of Rakai data,<sup>79</sup> investigators “constructed” couples from the entire study population based on the subject’s histories, archived serum samples from seroconverters, and viral genetics. This approach allowed them to detect the transmission of HIV within couples even when both partners were HIV seronegative at the beginning of the study, and thereby calculate infectivity by stage of infection. The average rate of HIV transmission was 0.0082/coital act within 2.5 months after seroconversion of the index partner, 0.0015 within 6–15 months, 0.0007 among HIV-prevalent index partners, and 0.0028, 6–25 months before the death of the index partner. In an accompanying commentary,<sup>80</sup> it was further calculated that nearly one-half of the HIV-transmission events observed could be ascribed to a

sex-partner with newly acquired HIV-infection; however, others have disputed this interpretation on the basis of unknown sexual behaviors, and generalizability to other populations with higher STI rates, and contracting HIV epidemics.<sup>81</sup> Similar objections have been raised by mathematical modelers.<sup>82,83</sup>

Nevertheless, in a study utilizing phylogenetic data (namely the generation of large volumes of sequences from the *pol* gene), epidemiological and cohort approaches were enhanced, and investigators from Vancouver showed that early infection accounted for approximately half of onward transmissions.<sup>84,85</sup>

With this extensive background of empiric and theoretical work on HIV-transmission, mostly based on measurements in blood, Johnson and Lewis conducted a comprehensive systematic review and meta-analysis of available data of the effects of genital tract infections on HIV-shedding in the genital tract.<sup>86</sup> Thirty-nine studies were examined. The odds of detecting HIV in the genital tract were increased in certain conditions (see Box 7.4).

Other infections and clinical conditions were found to have no significant effect on the detection of HIV, although HSV-2 shedding was found to increase the concentration of HIV, and GUD was found to increase the odds of HIV detection significantly, after exclusion of one biased study (OR 2.4, 95% CI 1.2–4.9).

The analysis showed that infections that are associated with significant increases in leukocyte concentrations in the genital tract are also associated with significant increases in HIV-shedding.

## Male Circumcision

The epidemiology of male circumcision is covered elsewhere in greater detail in Chapter 12, “Prevention of HIV and other sexually Transmitted Infections: Male Circumcision”.

Briefly, three RCTs showed a strong protective effect on HIV acquisition of about 60%. There were modest decreases in the incidence of HSV-2, *Trichomonas vaginalis*, papillomaviruses, and a small effect on syphilis. There were some indications of a greater efficacy of circumcision among men at higher risk in the Uganda trial (those with nonmarital partners, reporting transactional sex, or having a history of genital ulcers), namely, about 75% effect. This may be due in part to protecting against other STI, thus providing additional indirect protection against HIV. Overall, however, models estimate about 10–20% of the HIV infections prevented by male circumcision were due to efficacy against STI.

## Special Role of Genital Herpes (Especially HSV-2)

Studies of the role of HSV in HIV transmission were initially hampered by the low sensitivity of methods to detect HSV prior to the 1990s including virus isolation in tissue culture, cytologic examination, immunostaining, and antigen detection. The gold standard was viral culture, but the sensitivity dropped from nearly 100% in vesicular lesions to 30% in healing lesions.<sup>87</sup>

This all changed when PCR was developed for HSV,<sup>88,89</sup> and further refined for easy use in clinical settings.<sup>90,91</sup> Later, tests were developed to quantify the amount of herpes DNA.<sup>92</sup>

The new laboratory tools revolutionized investigations into the natural history of HSV-2, its world-wide distribution, and interactions with HIV.

In 2002, investigators used stored sera from the Mwanza trial<sup>93</sup> to show that HIV seroconversion was strongly associated with HSV-2 incidence; moreover, the next year Reynolds and colleagues in India demonstrated that hazard ratios for HIV incidence increased - the more recent the date of incident HSV-2 infection.<sup>94</sup> A substantial number of epidemiologic studies accumulated showing that prevalent HSV-2 was associated with a 2- to 4-fold increased risk of HIV acquisition.<sup>95</sup> In addition, most HIV-infected persons were also infected with HSV-2, and most experienced frequent subclinical and clinical reactivations, which elevated serum HIV-RNA levels. A systematic review and meta-analysis<sup>96</sup> showed HSV-2 positivity to be a significant risk factor for HIV acquisition in general populations of men (summary adjusted RR 2.7), women (RR3.1), and MSM (1.7).

The improved diagnosis of HSV-2 infection and improved control of STIs (especially chancroid and syphilis) clearly indicated that HSV-2 might be as important, or more important, than bacterial STI in promulgating the HIV epidemic,<sup>97</sup> and pointed the way toward the next step-evaluation of antiviral treatment of HSV-2 as a prevention strategy to reduce acquisition and transmission of HIV.

At the same time the biology and natural history of HSV-2 were becoming better understood, in particular, the frequency of subclinical reactivations, and the amount of HSV-2 and HIV shedding during these reactivations in coinfecting individuals.<sup>98–100</sup>

The next step evaluated, in three proof-of-concept RCTs, the effect of HSV-2 suppressive therapy with either 800 mg acyclovir daily or 1000 mg valacyclovir daily on HIV-1 genital or rectal shedding and plasma HIV-1 RNA. In these trials the strength and consistency of the observed reduction in HIV-1 replication and the biological plausibility of interactions between the viruses strongly suggested a causal relation between the replication of the two viruses<sup>101–103</sup> (Fig. 7.9).

Following these trials, Van de Perre and colleagues, in a comprehensive review,<sup>104</sup> explored the mechanisms that may operate to enhance reciprocal viral replication. Direct interactions could involve HIV-1 related immune deficiency, disruption of mucosal barrier by HSV infection/reactivation, HSV-induced

	HIV acquisition	HIV transmission

mucosal cell recruitment, transactivation of HIV-1 replication by HSV proteins, and immune modulation by HSV decoys. Indirect interactions might coexist through disturbances of the vaginal flora during HSV shedding and systemic immune activation. In coinfecting individuals, suppressive treatment reduces HIV-1 genital and systemic excretion. This finding is a likely result of efficacious prevention of HSV-2 reactivations, and perhaps of other herpes viruses.

Two very large RCTs were then conducted to assess the effect of acyclovir 400 mg twice daily on HIV incidence (the “acquisition link”) in 821 high-risk women in north-western Tanzania,<sup>105</sup> and women in various populations of Johannesburg (South Africa), Harare (Zimbabwe), Lusaka (Zambia), and MSM in San Francisco, Seattle, New York (USA), and Lima, Pucallpa, and Iquitos (Peru)—*n* = 3277 total.<sup>106</sup> No impact was observed in either trial, a profoundly disappointing result.

A randomized trial was next conducted to test “the transmission link”, by giving the same dose of acyclovir (400 mg twice daily) to serodiscordant couples for HIV (Partners in Prevention Trial). 3,408 couples were recruited at 14 sites in Africa. Despite a reduction in plasma HIV-RNA of 0.25log<sub>10</sub> copies per milliliter and a 75% reduction in GUD, there was no effect on the transmission of HIV-1, another profoundly disappointing result.<sup>107</sup>

It is possible that the dose of acyclovir used in these studies was not sufficient to reduce the HIV viral load (via reduction of HSV-2 reactivations) but enough to prevent HIV transmission, while still having sufficient effect to slow HIV disease progression. There is some evidence for both these hypotheses. First, higher doses of acyclovir (800 mg as a single dose), or valacyclovir (which has twice the half-life of acyclovir) have been associated with greater reductions in genital shedding of HIV-RNA<sup>101,103,108,109</sup> and second, acyclovir was shown to have a modest effect on HIV progression in a subsequent analysis of the Partners for Prevention trial<sup>110</sup>; the latter was not altogether surprising, a similar effect had been shown in the late 1990s,<sup>111,112</sup> presumably overshadowed at the time by the development of more powerful antivirals, directed specifically at HIV. Acyclovir has no direct effect on HIV replication, but in the meantime had been shown

to lower plasma HIV-1 RNA at any given CD4 cell count, when given daily for suppression of HSV-2 reactivations.<sup>113</sup>

Despite the disappointing results in the “acquisition” and “transmission” trials, to date there is no reason to doubt the enormous impact of HSV-2 on the HIV epidemic. HSV-2 is the leading cause of GUD worldwide. In Africa, HSV-2 seroprevalence in the general population ranges from 24% in West Africa to 74% in South Africa, mirroring the gradient of HIV infection rates.<sup>114</sup> Using seroprevalence data in mathematical models generated an estimate of 536 million infections worldwide, with 23 million new infections each year.<sup>115</sup> A study in Malawi<sup>116</sup> has shown that HSV-2 was already widespread in that country before the HIV epidemic and has not greatly been influenced by it. Sophisticated mathematical modeling<sup>117</sup> suggests that the role of HSV-2 as a biological cofactor in HIV acquisition and transmission may have contributed substantially to HIV, particularly by facilitating spread among the low-risk population with stable long-term sexual partnerships. In another modeling exercise, based on data from the Four Cities study,<sup>41</sup> it was also strongly suggested that HSV-2 therapy could potentially have a population-level impact on the incidence of HIV, especially in more concentrated epidemics. However, a substantial impact would require high coverage and long duration therapy, or very high symptom recognition and treatment-seeking behavior.<sup>118</sup>

In fact, the WHO published STI treatment guidelines in 2003,<sup>119</sup> which recommended that acyclovir should be included as a first-line GUD therapy in all countries where the relative prevalence of HSV-2 as an etiologic agent was 30% or higher. In 2009, an RCT in South Africa showed the benefits of early episodic acyclovir therapy (400 mg 3 times daily for 5 days), in terms of both ulcer healing, and reduction in HIV-lesional shedding.<sup>120</sup> A recent editorial emphasizes the importance of early initiation of episodic treatment in countries in the midst of an HIV/AIDS epidemic, where the natural history of HSV-2 infection has been radically altered by frequent recurrences and extended episodes.<sup>121</sup>

## A Return to Studies in MSM

At the beginning of this chapter, we discussed some of the shortcomings of early studies in MSM that attempted to infer causality for STI in HIV acquisition (the “acquisition” link).

Studies of STI/HIV interactions in MSM have a number of methodological limitations, including the same prime confounders as those in heterosexual populations, namely sexual behaviors. It is possible that there is a much greater variety of homosexual behavior(s), many of which are changing since the advent of ARV,<sup>122–126</sup> or under the influence of drugs and alcohol<sup>127–132</sup>; in addition, the behaviors of MSM in other non-Westernized societies have been poorly studied.<sup>133</sup> One recent prospective study controlled for many aspects of sexual behavior, and found anal gonorrhea (adjusted hazard ratio = 7.12, 95% CI 2.05–24.79) and anal warts (adjusted hazard ratio = 3.63, 95% CI 1.62–8.14) to be independently associated with HIV-acquisition.<sup>134</sup>

With respect to syphilis, a retrospective study of case records in Amsterdam revealed that a third of 81 HIV-positive patients had asymptomatic syphilis, a much higher percentage than in HIV-negative patients.<sup>135</sup> This accords with results obtained in Australia, where the incidence of syphilis was 5–10 times higher in HIV-positive than HIV-negative MSM.<sup>136</sup>

There are a few studies of the association of STI with HIV transmission in MSM (“the transmission link”).

A small study (n=7) of asymptomatic urethritis showed it to be independently associated with seminal HIV RNA shedding (adjusted OR 80.2) and with blood plasma viral load (adjusted OR 19.3)<sup>137</sup>; a larger study (n=55) of HIV-positive MSM not on ARV demonstrated that semen plasma viral loads were approximately 5-fold higher in those with gonococcal or chlamydial urethritis, compared to controls (4.27 log copies/ml versus 3.55 log copies/ml, respectively),<sup>138</sup> and a third showed drug resistant virus in semen to be 20-fold higher during gonorrhea, than following antibiotic treatment.<sup>139</sup>

The effects of syphilis on HIV viral load are inconsistent,<sup>140,141</sup> and syphilis does not appear to affect HIV disease progression, at least as measured by hazard of AIDS or death (hazard ratio 0.99).<sup>142</sup>

The only published references on HIV viral load in rectal mucosal secretions are from Zuckerman’s group in Lima, Peru and Seattle, Washington. In 27/64 MSM on ARV, they found higher median levels in rectal mucosal secretions (4.96 log copies/ml) than blood plasma (4.24 log copies) or seminal plasma (3.55 log copies).<sup>143</sup>

They took part in the Partners for Prevention trial of HSV-2 suppression, and found that valacyclovir resulted in a 0.16 log decrease in rectal HIV-1, and a 0.33 log decrease in plasma HIV-1 viral load, compared with respective values in the placebo arm, though it is unclear whether further studies on HIV-transmission in this group have been undertaken.<sup>144</sup>

Finally, circumcision does not appear to have much effect on STI or HIV in homosexual men, a result that is not entirely surprising, as it would only be expected to have a marked effect in MSM, whose sexual repertoire was entirely insertive.<sup>145,146</sup>

## Further Considerations

No one seriously disputes that HIV and STI influence each other in important ways, certainly at the level of the individual, and probably also at population level.

However, after the failure of five out of six African RCTs of bacterial STI control to prevent HIV, and even worse, the failure of the HSV-2 suppression trials—thought by many including the present author to be the strongest cofactor—investigators have been at a loss to explain the negative results. One of the chief proponents of circumcision—itself probably a crude debulking of the best target for pathogens—has called for a reassessment of what he views as a flawed hypothesis, namely that STI control could ever reduce HIV incidence.<sup>147</sup> Others claim that interventions were implemented during the wrong phases of most HIV

epidemics,<sup>148</sup> or just simply had multiple defects in trial design and implementation.<sup>149–152</sup> Thus far, little attention has been paid to the present state of ignorance of HSV-2 biology, and the biology and immunology of the reproductive, genitourinary, and GI tracts (including the rectum).

Austin Bradford Hill's famous considerations (and his invention, RCT) are probably both overinterpreted by those who would use them as criteria, and underappreciated by those who dismiss them as flawed. In fact, the heuristic value that epidemiologists place on them converges to zero as the complexity of a causal system, and the uncertainty about the true causal system increase.<sup>153,154</sup>

Finally, it seems increasingly likely that the interactions between HIV and STI are multifactorial, and that not enough emphasis has been placed on the complex social construction of sexual behaviors, including the situations that place individuals "at risk of risks".<sup>155</sup>

### Summary

Where possible the chapter is written as a narrative, highlighting themes, advances in laboratory techniques, as they occurred, and the population experiments that followed. It starts with the first description of AIDS and continues to the present.

In the 1980s and early 1990s, observational and other studies suggested an association between the presence of STIs and human immunodeficiency virus (HIV) transmission, by increasing either the infectiousness of the index case, the susceptibility of the partner, or both ("Epidemiological synergy", Wasserheit, 1992). However, the hypothesis that control of STIs can prevent the spread of HIV in populations has been extensively tested in community RCTs and is not supported by evidence in 7 of 8 trials. The equivocal results highlight the difficulty in assessing the effects of a single intervention and multiple causation, as well as the possible differential effects of STIs in early, mature, and late phases of an HIV epidemic. HIV and HSV-2 are known to be involved in a particularly vicious circle, with HIV facilitating acquisition and reactivation of HSV, and HSV in turn enhancing HIV acquisition and replication. However, several very large trials of HSV suppression have failed to demonstrate an effect on HIV acquisition, a profoundly disappointing result that remains perplexing. It has become evident that HSV biology is not well-understood. In contrast, three very large trials of circumcision in Africa have shown a remarkable, strong, and consistent protective effect of 50–60% on HIV acquisition (and some STIs). Finally, it seems increasingly likely that the interactions between HIV and STI are multifactorial, and that not enough emphasis has been placed on the complex social construction of sexual behaviors, including the situations that place individuals "at risk of risks".

## Prevention Strategies for the Control of Sexually Transmitted Infections

Johannes van Dam

### Introduction

Sexually transmitted infections (STIs), including HIV infection, continue to be a major public health problem in many countries in the world, despite the availability of effective interventions to prevent acquisition and transmission of STIs and of effective antibiotics to treat and cure bacterial infections. Approaches to prevention and control of STIs and HIV infection differ according to the epidemiological situation, the cultural environment, the availability of resources, and the priority allocated to this group of diseases by health planners and decision makers. This chapter presents a conceptual framework for STI/HIV prevention and control, followed by a discussion of strategies for the prevention of infection and for case management. The importance of both individual and population level intervention strategies will be discussed.

### Conceptual Framework

#### DETERMINANTS OF STI AND HIV TRANSMISSION

At the most basic level, the STI and HIV situation in a population is determined by: (i) the rate of exposure of susceptible individuals to infection; (ii) the likelihood that such exposure results in infection; and (iii) the length of time that a newly infected individual remains infectious and, thus, able to spread the infection. This has been described in the following mathematical model:  $R_0 = c \times \beta \times D$ .<sup>1</sup>  $R_0$  is the reproductive rate of an infection or the mean number of secondary cases that will arise from any infected individual.

For situations where  $R_0$  is greater than one, the infection will continue to spread and incidence increases. When  $R_0$  is smaller than one, the incidence is decreasing and the infection will disappear from a population. The objective of all STI and prevention strategies is to reduce  $R_0$  to less than one, by influencing  $c$ ,  $\beta$ , or  $D$ , or, more likely, a combination of these.  $D$  is the duration of infectiousness;  $c$  is the average rate of exposure of a susceptible individual to an infectious partner and is thus determined by the rate of partner change, as well as the likelihood

that such partners are infected.  $\beta$  is the average likelihood of infection, when exposed to an infectious person.

STIs are not uniformly distributed over a community since behavioral characteristics differ between individuals and between subgroups in a population. Sexual behaviors differ, as do the number of sex partners and the rate of partners change, which in turn represent different levels of risk of infection. Individuals with the highest rates of partner change contribute disproportionately to the spread of STIs and are often referred to as “core transmitters”.<sup>2,3</sup> To understand the STI situation in a population, one also needs to know more about the patterns of sex partner mixing and of sexual networks. Consecutive partnerships are clearly less risky for the transmission of most STIs than are concurrent partnerships, which have been shown in mathematical models and clinical practice to dramatically increase the incidence of HIV infection and other STIs.<sup>4,5</sup> If individuals with high rates of partner change have sex with others who themselves have many partners, the potential for initial rapid spread is very high. This is especially the case in “dense” sexual networks, where there are many different partnerships in a short period of time.<sup>6</sup> Where individuals have partners mostly within their own social and behavioral group (so-called “assortative mixing”), spread of infections tends to be limited to the group. If some of these individuals have partners outside their own social group (also called “dissortative mixing”), STIs have the potential to spread more widely through a population, although they are likely to spread more slowly.<sup>7,8</sup>

From a public health perspective, effective interventions that reach individuals with high rates of partner change, who are in dense sexual networks with assortative mixing are likely to have the highest impact. One of the challenges for STI and HIV prevention programs is to identify and reach such individuals.

With the advent of effective antimicrobial agents in the 1950s and 1960s, STI control efforts focused for the most part on the clinical care of symptomatic individuals while relatively little attention was paid to behavioral interventions. Prevention was usually restricted to limited education of patients by clinicians to prevent future infections and occasionally to ensure partner

notification and treatment. The emergence and recognition of a number of viral STIs, and especially HIV infection, have underscored the importance of prevention. STI and HIV prevention efforts initially focused heavily on the individual, promoting safer sexual behavior, that is, abstinence, delayed onset of sexual activity for youth, reduction of the number of sex partners, and use of a barrier method to prevent infection, such as the male or female condom. It is now widely accepted that the social, cultural, and economic determinants of behavior need to be taken into account and, where possible, addressed.<sup>9</sup> Gender roles and inequities, power relations in sexual relationships, economic dependence, work-related migration, illiteracy, lack of access to information, and poverty all contribute to risky sexual behaviors. Many women, for instance, are well aware that they are at risk of acquiring an STI or HIV infection from their husbands, but are not in a situation to safely and effectively negotiate condom use.<sup>10</sup> For interventions targeting individual behavior to be successful, it is important that these be combined with community or population level approaches. In the absence of an enabling and supportive environment, many individuals may be unable or unwilling to adopt safer behaviors.

## INTERVENTION STRATEGIES TO PREVENT AND CONTROL STIs AND HIV INFECTION

As mentioned earlier, STI and HIV prevention strategies seek to reduce the reproductive rate of an infection by shortening the duration of infectivity, by reducing exposure of susceptible individuals to infection, and by lowering the efficiency of

**Table 8.1:** Basic Strategies for Prevention and Control of STIs and Sexually Transmitted HIV Infection<sup>11</sup>

*Decrease duration of infectivity (prevent further transmission and complications)*

- Treatment (curative or suppressive)
- Early treatment (case finding)
- Vaccine (therapeutic)

*Decrease exposure of susceptible individuals to infection*

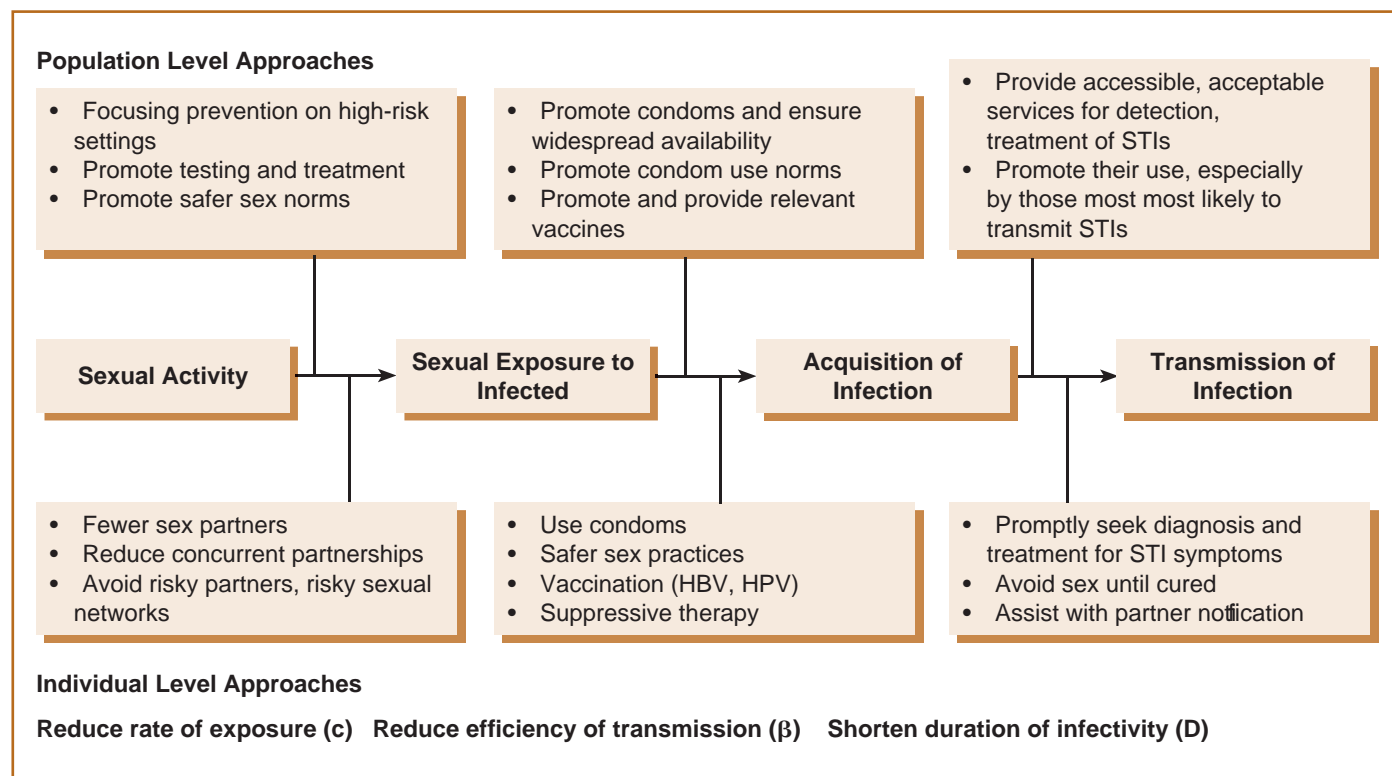

- Awareness/behavioral change interventions for susceptible individuals
- Behavioral change interventions for infected persons (especially for persistent viral infections)

*Decrease efficiency of transmission per exposure*

- Use of barrier methods
- Vaccine (protective)
- Use of microbicides

transmission for each such exposure. Basic strategies are summarized in Table 8.1.

The above strategies are both biomedical and behavioral in nature. While a vaccine offering protection against HIV has been elusive, a protective vaccine against Hepatitis B Virus (HBV) has been available for many years and in 2006 a vaccine against the most common carcinogenic strains of human papillomavirus (HPV) was approved for use in the UK, the USA, and in other countries.<sup>12</sup> In addition, for control programs to be successful, a combination of both individual and population level approaches is crucial. This conceptual framework is presented in Figure 8.1, which illustrates how both

**Fig. 8.1:** Individual and population-level approaches to STI and HIV prevention.<sup>13</sup>

individual and population level approaches act synergistically to prevent and control STIs, including HIV infection. It is important to note that for communicable diseases, individual interventions may well have an effect at the level of the population. For instance, effective treatment of infected individuals will result in a reduction of the prevalence of infection, and thus in reduced exposure of susceptible individuals to infected individuals.

For maximum impact, STI and HIV control programs require the implementation of a number of different interventions, as illustrated above. Few countries have been able to do so successfully, and it has proved difficult to overcome the social, cultural, religious, and above all resource constraints that prevail in many countries in the industrialized and the developing world. The Piot-Fransen model has frequently been used, in various adaptations, to demonstrate the results of insufficient, inadequate, or inappropriate program implementation. Figure 8.2 shows the cumulative effect of asymptomatic infections, poor symptom recognition, inappropriate healthcare seeking behavior, and inadequate clinical care, and demonstrates how, in many countries, only a small fraction of individuals infected with an STI in a population receives effective treatment. For instance, a study in South Africa showed that 25% of women surveyed were infected with at least one of the following infections: *Trichomonas vaginalis*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or *Treponema pallidum*. Of these women, 48% were asymptomatic, 50% were symptomatic but not seeking care, 1.7% were symptomatic and would seek care, while only 0.3%

were actually seeking care the day they were surveyed.<sup>14</sup> Findings like this underscore the importance of a holistic, comprehensive approach to STI and HIV prevention and control. For instance, improving case management of symptomatic patients seeking medical care will neither address the problems of large numbers of asymptomatically infected persons, nor that of inappropriate healthcare seeking behavior or lack of access to good quality healthcare services.

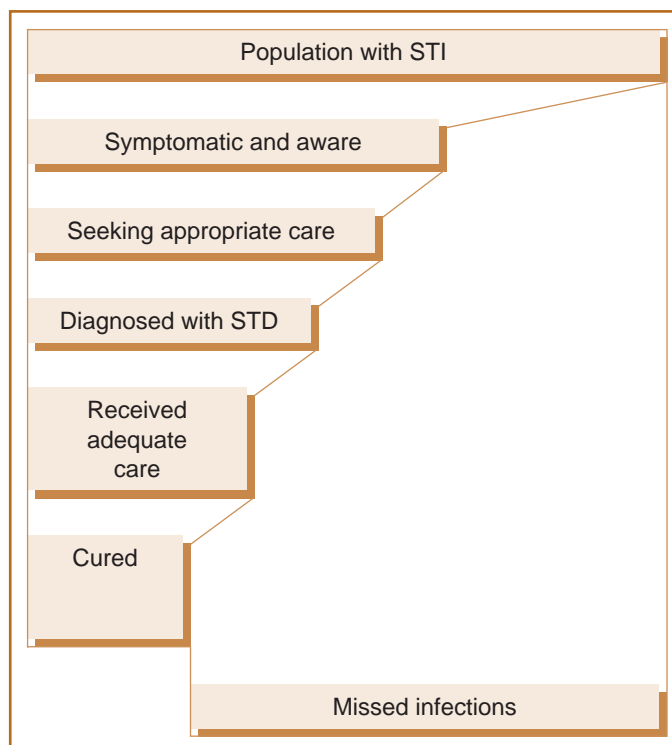

## Preventing New Infections

New infections can be prevented by reducing the prevalence of infections in the community, the use of preventive vaccines, such as those for HBV and HPV infection, and/or a reduction in or avoiding risk behavior at the individual level. Good quality effective clinical services are needed to reduce the prevalence of curable STIs, through the management and treatment of symptomatic and asymptomatic individuals with STIs. However, many STIs are of viral origin and thus currently not curable, and besides, clinical services are unlikely to identify and treat all individuals with curable infection. Thus, behavioral interventions remain crucial for the control of STIs and HIV infection.

The objective of such interventions is to reduce as much as possible the risk of infection through the adoption and maintenance of safer sexual behaviors. Examples of such behaviors are: abstinence, delay of sexual debut, nonpenetrative forms of sexual intercourse, reduction of the number of one's sex partners, and the use of barrier methods, such as the male and female condom or, possibly, microbicides.

For any of these behaviors to be adopted and maintained, individuals need not only to be aware of the existence of STIs, including HIV infection; they also need to recognize their own risk of infection. They need to know about safer alternatives and they need to have the means to implement these safer behaviors. In addition, the environment needs to be conducive to such behaviors.<sup>16–17</sup> Individual behavior is to a large extent influenced by the social and cultural context, that is, by partners, the extended family, peers, the community and, broadly speaking, existing norms. For maximum effectiveness, prevention programs should intervene at these different levels, and promote norms and behaviors that reduce the risk of acquisition and transmission of STIs. For instance, structural and policy interventions should support and mutually reinforce outreach by hospitals, community mobilization, and inter-personal interventions, such as peer outreach, couple counselling, or individual counseling.<sup>18</sup> Such interventions should promote delayed sexual initiation for those who are not yet sexually active; monogamy for those who are sexually active; avoiding concurrent sexual partnerships; and normalize the use of condoms.

An example of a multilevel intervention is the national HIV/AIDS prevention and control program in Thailand, which consists of, among others, a 100% condom use policy in brothels, a public education campaign, effective and easily available STI services, and outreach to sex workers and clients. It is credited with a substantial reduction in both STI and HIV infection rates in the Thai military.<sup>19,20</sup>

**Fig. 8.2:** The effect of poor healthcare seeking behavior and ineffective STD services on STI prevalence.<sup>15</sup>

The most effective approaches to prevention campaigns employ, thus, a combination of multilevel interventions, where the different interventions address the different influences on the individual. While mass media can be used effectively to raise awareness at the level of the population or a subgroup and may even influence cultural norms, these are likely to be much less effective in creating a good understanding of personal risk and vulnerability or in exploring options to reduce such risk.<sup>21</sup> When addressing the needs of marginalized or other hard-to-reach populations, interpersonal communication approaches are of the utmost importance. A successful communication program needs to identify and research its target audience, develop and pre-test messages specific to the objectives of the program and to the intended audience, and identify appropriate channels of communication.

### Improving Healthcare Seeking Behavior

An important element of an STI communication program is to raise awareness of the symptoms of STIs and the importance of early and appropriate treatment. Barriers to seeking appropriate and early treatment exist in many countries. The most common of these are ignorance of signs and symptoms of STIs, the stigma associated with STIs, and the lack of accessible and acceptable clinical services. The latter is often related to the poor quality of care offered through many such services and the frequently pejorative attitudes of healthcare workers to people with STIs.

Prior to initiating efforts to improve healthcare seeking behavior, it is important to do diagnostic research to identify the barriers to appropriate healthcare seeking behavior. For instance, integrating STI care with other, readily available services might reduce the degree to which stigma prevents people from seeking treatment. But improving the quality of care offered through public and private facilities, ensuring the availability of effective antibiotic treatment, and addressing the attitudes of healthcare workers may be necessary prerequisites to ensure the success of a communication program seeking to improve healthcare seeking behavior.

### Private Sector Involvement

In many countries, both in the industrialized and the developing world, the private sector is an important source of delivery of health services, and many STI patients prefer private sector providers as being more accessible, rapid, efficient, and anonymous.<sup>22</sup> There is now a slowly growing body of experience of interventions that seek to increase the role of the private sector in STI care and treatment. This experience ranges from voucher schemes to address issue of affordability, franchised services to increase access and quality, and interventions that seek to improve services offered by large employers to their workforce, such as the gold mining industry. Voucher schemes tend to be expensive to administer, although they might be cost-effective when used with high-risk populations.<sup>23</sup> Franchised services, where providers operate under a branded name and are

supported by advertising, training, supervision, and supplies, have been found to increase client satisfaction and to result in some improved health outcomes, although quality assurance remained an issue.<sup>24</sup> More research is needed to identify and evaluate approaches to more effectively utilize the private sector in the provision of quality STI services.

### Clinical Management of STIs

One of the cornerstones of STI control is the effective management of STIs. Early diagnosis and treatment prevent further transmission and the development of complications and late sequelae, and it has the potential to greatly reduce HIV transmission. Ideally, such case management is based on an etiological diagnosis and the provision of effective antimicrobial agents, combined with one-on-one health education and counseling for treatment adherence, abstinence during treatment, partner notification, and behavioral change, including condom promotion. Very few places in the world have the resources to provide such comprehensive case management for all or even the majority of people with symptomatic STIs. In most resource-constrained settings, there is little or no access to laboratory facilities needed for an etiological diagnosis of STIs, well-trained staff is in short supply while the workload is high, resulting in very short patient-provider interactions. Management of STI patients is thus often based on a clinical approach, that is: history and physical examination, supported by simple laboratory tests, if available.<sup>25</sup>

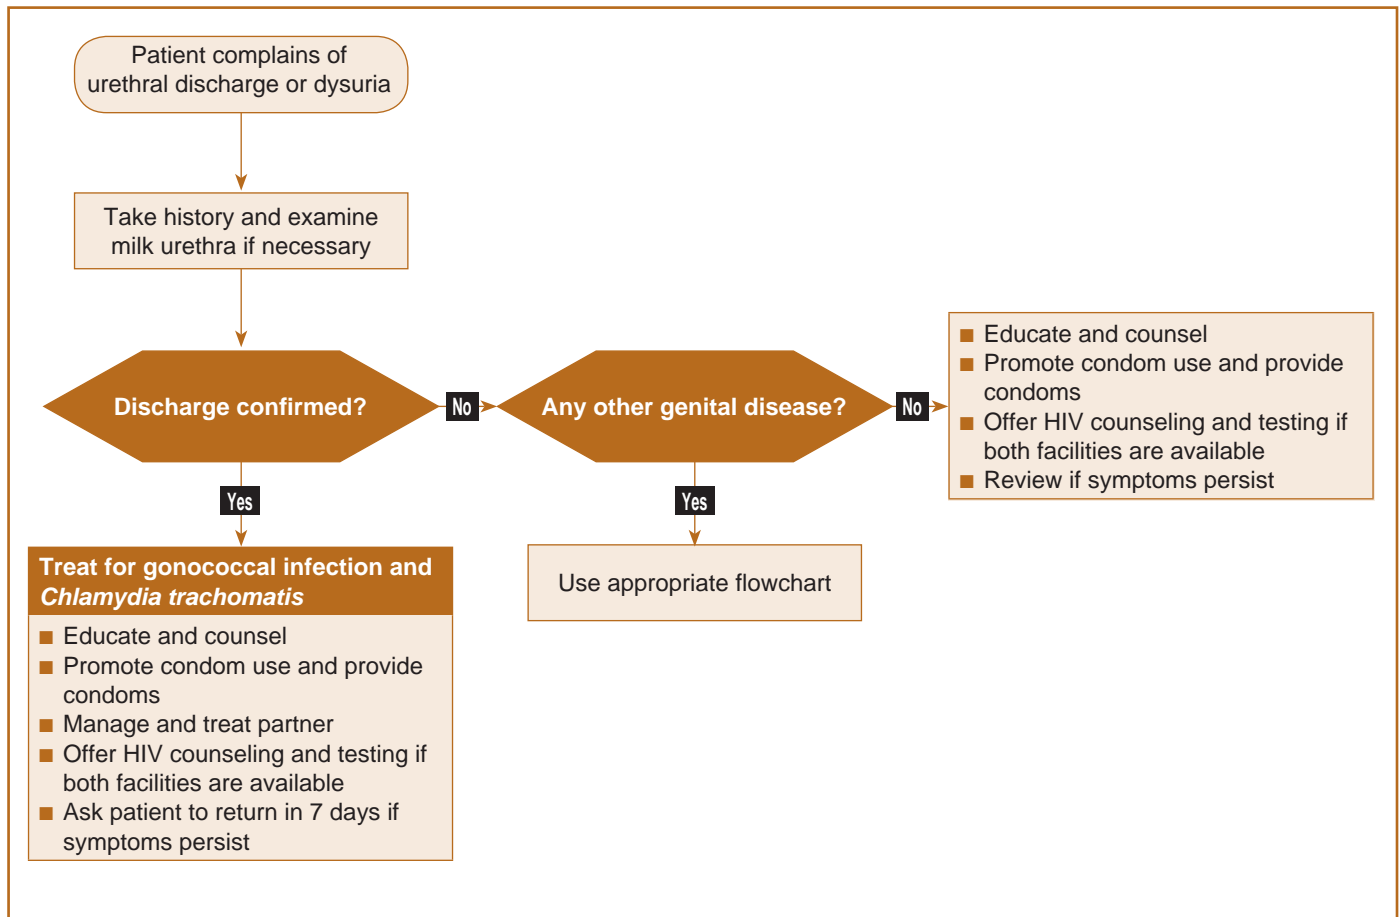

Syndromic approaches to STI case management have been developed and evaluated during the last 20 years. The syndromic approach is based on the following:

- (1) The recognition of relatively consistent and characteristic combinations of signs and symptoms (syndromes) with which STIs commonly present.
- (2) Knowledge of the most common local etiologies of the different syndromes.
- (3) Knowledge of the antimicrobial susceptibility patterns of these organisms.
- (4) Knowledge of the behavior and demographic characteristics of people with STIs.

Cure of patients with bacterial STIs is achieved through recognition of the presenting syndrome and provision of effective antibiotics against the most important causative organisms.<sup>26</sup> Promoting compliance with the treatment, counseling for risk reduction, condom promotion, and contact notification and treatment (the four “C’s”) are essential components of comprehensive care. Figure 8.3 provides an example of an algorithm to address the syndrome of urethral discharge, in a situation where microscopy is not available.

Where possible, laboratory tests can be added to increase the specificity of the algorithm. For instance, adding a microscopic examination of the gram-stained smear of the urethral exudates might reveal the presence or absence of gram-negative intracellular diplococci (ICDC). Where ICDC are present, treatment for both gonorrhea and chlamydial infection is indicated, while in the

**Fig. 8.3:** Algorithm for the management of urethral discharge. *Source:* WHO, Guidelines for the Management of Sexually Transmitted Infections, WHO 2003, Geneva, Switzerland.

absence of ICDC, treatment for gonorrhea can be omitted.

The syndromic approach has proven to be highly effective in the management of men with urethral discharge and of men and women with genital ulcer disease (GUD) of bacterial origin. Validation studies in Côte d'Ivoire and Kigali, Rwanda, for instance, showed cure rates of 100 and 99 percent, respectively, for genital ulcers using a syndromic approach.<sup>28,29</sup> Reports of increased prevalence of herpes simplex virus type 2 (HSV-2) among patients with GUD from, among others, Uganda and South Africa suggest that the currently recommended protocols for the syndromic management of GUD may be less effective in such situations.<sup>30,31</sup> In situations where HSV-2 is an important cause of genital ulceration, it may be indicated to add treatment for HSV-2 to the syndromic management of patients with GUD.<sup>32</sup> While the syndromic approach to the management of vaginal discharge is effective in addressing vaginitis, the most common cause of such discharge, it has proven to have low specificity and a low positive predictive value when used for the detection and management of cervical infections. Adding a locally appropriate risk assessment may improve the specificity somewhat, but the positive predictive value remains low in most situations.<sup>33,34</sup>

Rapid and simple laboratory tests that can detect gonococcal and chlamydial infection are urgently needed for the management of women, and also men, with asymptomatic gonococcal and chlamydial infections.

### Detection and Treatment of Asymptomatic Infections

A large proportion of women infected with a sexually transmitted organism are asymptomatic or only mildly symptomatic.<sup>11</sup> Large population-based studies have contributed to our understanding of the extent to which nonulcerative STIs in both men and women can be asymptomatic. For instance, 53% of men and 66% of women with gonorrhea, 92% of men and 76% of women with *Chlamydia*, and over 80% of women with trichomoniasis or bacterial vaginosis were asymptomatic in Rakai, Uganda.<sup>35</sup> Only 15% of men with either gonorrhea or chlamydial infection on a sample of rural men in Mwanza, Tanzania, were symptomatic.<sup>36</sup>

Where resources permit and diagnostic tests are available, case finding and screening can be implemented. Case finding and screening programs should initially focus on gonococcal

and chlamydial cervical infections, and on syphilis in men and women. The cost-effectiveness of such programs can be increased by identifying individuals at increased risk of infection through the application of a risk assessment, and to apply screening tests to individuals with a higher prior probability of being infected.<sup>26</sup> Screening of antenatal clinic (ANC) attenders for syphilis has been demonstrated to be a cost-effective public health intervention, even when the prevalence of syphilis among pregnant women is 1:20,000.<sup>37,38</sup> Even though screening of ANC attenders is a highly cost-effective public health intervention, programs are absent or inefficient in many countries. In Nairobi, Kenya, logistical and managerial constraints led to a situation where only 1 out of 11 women with reactive syphilis serology received treatment, whereas for 92% of ANC attenders blood was not taken, or, if it was taken, no results were available.<sup>39</sup> An important priority for any STI control program should be to implement a maternal syphilis screening and treatment program, or where such a screening program exists, to strengthen it to ensure complete coverage of all ANC attenders.

The syndromic approach by definition fails to identify asymptotically infected individuals. In situations where the prevalence of asymptomatic infections is high and where laboratory screening is not possible, mass or presumptive treatment has been successful in rapidly reducing the prevalence of STIs to very low levels.<sup>40</sup> Periodic presumptive STI treatment of sex workers in South Africa was successful not only in reducing rates of STIs in sex workers, but was also associated with a reduced incidence of STIs in male mine workers in the vicinity of the treatment site.<sup>41</sup> However, upon cessation of a mass treatment program, rates of infection tend to revert to preintervention levels in a relatively short period of time.<sup>42,43</sup> There is currently great interest in the application of so-called hybrid approaches, combining periodic presumptive treatment, especially of members of “core groups” with effective behavior change interventions, condom promotion, and good quality clinical services. Such a combination of interventions might allow for a much increased treatment interval in the periodic presumptive treatment program, while still keeping the prevalence of STIs low. Research is currently underway to examine the impact of such programs in Zimbabwe, Zambia, and South Africa.

An important group of potentially asymptomatic, but infected, individuals are the sex partners of a symptomatic patient. Ideally, the partners of an index patient are evaluated and the presence of an infection is established before treatment is initiated. Diagnostic tests, however, are not available for the majority of such contacts, and infection can thus rarely be confirmed. In such cases, epidemiological treatment of the partner or partners is indicated. This is treatment without a proper diagnosis, but based on the likelihood of a person being infected, and is recommended for the partner(s) of patients with gonorrhea, chlamydial infection, syphilis, and chancroid, and of patients with the syndrome of urethral discharge, GUD, or pelvic inflammatory disease.<sup>26</sup> Innovative approaches to partner treatment, such as expedited treatment where index patients are offered medication to give

to his or her partners have been associated with reduced rates of persistent or recurrent gonorrhea or chlamydial infection.<sup>44</sup> Great care should be taken to ensure that these approaches to the management of asymptotically infected individuals are gender sensitive and do not contribute to stigmatization of women.

## STI Treatment and HIV Prevention

A number of observational studies provide evidence that both ulcerative and nonulcerative STIs facilitate the transmission and acquisition of HIV infection.<sup>45</sup> Shedding of HIV in genital secretions is increased in the presence of STI-related inflammatory reactions and exudates from lesions, thus potentially rendering HIV-infected persons with concurrent STIs more infectious.<sup>46,47</sup> Cohen et al. demonstrated an eight-fold increase in viral load in seminal plasma in the presence of urethritis, and a subsequent reduction in viral load after treatment of the urethritis in Malawi.<sup>48</sup> In women with gonorrhea or chlamydial infection, there is an increase in the number of CD4+ lymphocytes (the target cell for HIV infection) in the endocervix.<sup>49</sup> Lastly, a community-based STD treatment trial in Mwanza, Tanzania, demonstrated a 42% reduction in HIV incidence in the intervention communities compared to the control communities.<sup>50</sup> This suggests that the benefits of effective STD treatment might be manifold; apart from the immediate benefit to the person infected, there might be a dynamic, population effect in reducing further transmission of the STIs as well as of HIV infection. Subsequent STI prevention and treatment trials did not result in a reduction in HIV incidence. The extent to which STD treatment might affect HIV transmission depends upon the background prevalence of HIV in the community, on the prevalence of high-risk sexual behavior, and on the types of STIs present in the community.<sup>51,52</sup>

## Clinical Management of HIV/AIDS

Treatment of AIDS with antiretroviral therapy is discussed in Chapter 68. Even with highly active antiretroviral therapy (HAART), it is currently not possible to eradicate HIV from the body, but it is nevertheless possible to reduce the viral load in the peripheral blood to very low or undetectable levels and HAART has been associated with a 50% reduction in morbidity and mortality.<sup>53,54</sup> In Rakai, Uganda, a direct relationship between plasma viral load and transmission of HIV was found, with the probability of transmission per sex act increasing from 0.0001 at viral loads of less than 1,700 copies/mL to 0.0023 per act when the viral load in the infected partner was 38,500 copies/mL or more.<sup>55</sup> While HAART also results in a reduction in the level of HIV-1 virions in seminal fluid, it has nevertheless been possible to detect replication-competent, and thus potentially infectious virus in the seminal fluid of men without detectable viral RNA in plasma.<sup>56</sup> It has been hypothesized that antiretroviral therapy might, in addition to conferring a benefit to the person taking the treatment, also contribute to reduced HIV transmission. Further study is needed to evaluate the impact on HIV transmission of antiretroviral therapy.

Recent findings from intervention trials have demonstrated the potential impact of antiretroviral based prevention approaches on HIV transmission. Studies among men who have sex with men,<sup>57</sup> heterosexual men and women,<sup>58</sup> and discordant couples<sup>59</sup> have all shown a protective effect of oral pre-exposure prophylaxis, ranging from 44% to 72%. Early treatment with ART of the infected partner in discordant couples reduced transmission by 96% in a large multi-country randomized controlled trial.<sup>60</sup>

## Conclusion

Successful prevention and control of STIs and HIV infection require the implementation of a combination of approaches, tailored to the epidemiological and resource situation in a country, while taking into account the cultural environment. Multilevel approaches are required for successful prevention programs, addressing both individual behavior as well as the sociocultural context within which individuals live and act. Early diagnosis and treatment of symptomatic STIs and, where possible, management of asymptomatic infections further contribute to prevention by reducing the transmissibility of HIV infection. Delivery of facility-based clinical services can be reinforced by periodic presumptive treatment of individuals at increased risk of infection, especially in situations where laboratory screening for case finding is not feasible. The syndromic approach to STD case management is still the most feasible option for the clinical management of the large majority of patients with symptomatic STIs, although rapid and simple diagnostic tests are essential for the effective management of gonococcal and chlamydial infections in women and to a lesser extent in men. A majority of patients with STIs seek care outside the public sector, and involvement of the private sector in improving the quality of STI service delivery is therefore crucial. Screening for the detection of syphilis in pregnant women is a highly cost-effective public health intervention and should be implemented or strengthened with the greatest urgency. Recent findings from HIV prevention trials have shown the potential for the use of ART-based prevention approaches to reduce both acquisition by HIV-uninfected individuals and transmission by HIV-infected individuals, through pre-exposure prophylaxis and early treatment, respectively. Lastly, prevention programs should be developed and implemented in a gender-sensitive way, appropriate to the needs of both men and women, while taking care not to stigmatize women.

### Summary

Successful prevention of sexually transmitted infections requires a combination of individual and population-level approaches that focus on reducing the risk of acquisition and transmission of infection. Both primary and secondary prevention are of crucial importance, and both the public and the private sectors have a role to play. Recent findings have underscored the importance of pre-exposure prophylaxis as well as early treatment in the primary prevention of HIV infection.

## Behavioral and Counseling Aspects of Sexually Transmitted Infections (Including HIV)

Michael W. Ross • Lena Nilsson Schönnesson

### Introduction

This chapter attempts to explain the beliefs underlying psychological reactions to sexually transmitted infections (STIs) and the reasons for psychological problems, as well as approaches to counseling them when they occur. There are a number of reasons why counseling is an integral part of treating patients with STIs including HIV. First, the management of the illness, and the prevention of further infection of others or reinfection, is based on a number of behaviors that may be positively influenced by counseling. These include cessation of unsafe sexual behavior and other actions likely to transmit pathogens, adherence to medication, and alteration of current and future sexual behavior to prevent reinfection after treatment. Second, STIs are different from most other conditions in being stigmatizing; indeed, even talking about sexual behavior, let alone about contracting an STI, causes difficulty for some health practitioners. In the case of widely publicized STIs, such as HIV infection and genital herpes, the stigmatization is sufficiently severe as to lead to overt discrimination. The degree of stigmatization may lead to psychological harm, including depression, anxiety or loss of self-esteem, as well as loss of social supports. While important in themselves, these factors in turn are likely to negatively influence risk behavior change, adherence with medication and other behavioral requirements for successful treatment, and avoidance of reinfection.

### Meaning of STIs to an Individual

Perhaps the earliest recorded account of an STI, probably syphilis, was in China in 6237 BC<sup>1</sup> yet little of a scientific nature has been written about the meaning of STI infection to the individual, and little empirical research has been carried out on this area.<sup>2</sup> In discussing the meaning of STIs to the individual, there appear to be at least five separate attributions in modern society.<sup>3</sup>

1. STIs are a deserved outcome of indiscriminate sexual behavior and punishment for sexual sins.
2. STIs are a consequence of individual inadequacy that leads to sexually indiscriminate behavior.

3. STIs are a consequence of a breakdown in traditional social values and rapid social change.
4. STIs are the result of an individual coming into intimate contact with a virulent pathogen.
5. STIs are a sign of being sexually active and a matter of pride.

There is a hierarchy of blame from attribution 1 to attribution 5. With the exception of attribution 5, the level of blame roughly parallels a similar hierarchy of the degree to which the individuals see themselves as responsible for the infection. However, it is important to recognize that different models will apply in different cultures and subcultures, and will depend on the degree to which there is a psychological investment in sexual behavior. Equally importantly, the meaning of STIs to the patient and to a lesser degree to the health practitioner will affect not only the adherence with treatment but also the psychological response to infection and probably the subsequent risks of exposure to STIs the patient takes. Diagnosing the psychological difficulties surrounding STIs will be made easier if the practitioner is able to assess the patient's understanding of what it means for her or him to have an STI. The practitioner can then in the counseling process intervene more effectively.<sup>3</sup>

### Counseling

#### CONCEPT OF COUNSELING

Counseling is sometimes a vague term which is loosely applied in health practice and is occasionally used synonymously with "talking". However, counseling is never *aimless* talking<sup>4</sup> but is a process of helping a person taking charge of his/her own life by developing the ability to make wise and realistic decisions, altering his/her own behavior to produce desirable consequences, and providing information. Counseling is an issue-centered and goal-oriented interaction and a confidential dialogue between a person and a care provider, in which the counselor offers his/her time, attention, and respect. Good counseling, including providing information that is tailored to the individual patient's need, helps the patient to be autonomous, i.e. to be able to choose, make decisions, and be responsible for his/her own actions.

## LEVELS OF COMMUNICATION IN COUNSELING

Counseling encompasses three levels of communication: permission, limited information, and specific suggestions. These levels correspond to three of the four levels of the PLISSIT model.<sup>5</sup> Originally, it was developed as a model of intervention of sexual health counseling. ‘P’ stands for a permissive atmosphere in which the patient feels free to talk about his/her concerns, including sexual issues. ‘LI’ stands for limited information. Giving information often goes hand in hand with giving permission. Frequently, this information serves to dispel myths or misconceptions. The information should be limited to specific facts directly relevant to the patient’s particular concerns. ‘SS’ refers to specific suggestions. Within the STI counseling setting, this level refers to STI-related risk reduction plans. ‘IT’ stands for intensive therapy. This level is not included in STI counseling, since the provision of intensive therapy is not part of the role of a STI counselor. These levels of communication require STI and HIV-related knowledge, self-awareness, and counseling skills and techniques on the part of the counselor.

### Self-Awareness

Self-awareness helps the counselor to: be aware of his/her own attitudes and values that (s)he brings to STI counseling; feel comfortable when discussing sensitive issues such as sexualities; separate his/her own feelings from those of the patient; and create a permissive attitude during the counseling session.

From the social environment where we grow, we develop certain stereotypes and prejudices about other people and other groups that have a major impact on our social and interpersonal interactions with other. These stereotypes and prejudices are reflected in our attitudes composing of 3 components: our thoughts, beliefs, and ideas (the cognitive component) quite often evoke feelings. Feelings (the emotional component) associated with attitudes can even turn into behavioral acts (the behavioral component) such as bashing commercial sex workers, men who have sex with men (MSM), certain ethnic groups, etc. Closely related to attitudes are values. They refer to beliefs that help the individual determine what is right and wrong, good or bad, and what is to be cherished. Attitudes and values exist within cultural and time contexts. Just as patients bring their attitudes and values to the counseling session, so do counselors. For example, within the STI context, the range of meanings of STIs described above are just as applicable for counselors. On the one hand, the counselor whose attribution of STIs is as a punishment will discourage avoidance of risks because the “punishment” is preordained and presumably unavoidable. Nor will any distinction be made between safer and unsafe sexual acts because the “punishment” is seen as being of for sexual activity, not specific sexual acts! On the other hand, the counselor who believes that sexuality is important and that STIs are just another infection may have less motivation to encourage individuals to modify their behaviors. Either extreme is unhelpful. Where counselors see sexual contact in moral or ideological terms –

the counselors need to address their own values and attitudes. Otherwise, the interaction between patients and counselors who hold conflicting attributions of HIV or STIs may also lead to tension, anger, transference and counter-transference issues, and to resistance to taking advice or to treatment, particularly where more divergent attributions are held. Our attitudes and values can also be challenged by the patient’s mode of functioning and attitudinal and value systems may clash when patient and counselor have different cultural/ethnic backgrounds. In other words, what is important to keep in mind is that our attitudes and values as counselors will affect our approach to our patients, and that our personal attitudes will interact with those of our patients. To be effective STI counselors, there is a need to be as aware as possible of one’s attitudes and values, in particular in relation to vulnerable groups, sexualities, and STIs.

It is crucial to remember that counselors have a right to their personal attitudes, morality, and values. But they should not impose their attitudes and values upon the patients. Counseling sessions may evoke feelings not only within the patient but also within the counselor. While the counselor cannot be held responsible for his/her feelings, (s)he has the responsibility for what (s)he does with his/her feelings.

### Counseling Skills and Techniques

Establishing and maintaining a professional relationship is crucial in all counseling. Unlike casual conversation, information that is exchanged and obtained in counseling is specific, focused, and serves a purpose. The STI counselor enters the private world of a patient and may have to facilitate the patient in being very explicit in describing sexual patterns of behaviors. Basic counseling skills are essential to conduct a dialogue with the patient. They can enable the patient to explore his/her problem, reach a better understanding of the problem, deal with her/his related feelings and concerns, evaluate alternatives, make choices and take action. Examples of counseling skills are empathy, attention, and listening.

The ability to be empathic is one of the crucial skills in counseling. Empathy is defined as including: (i) the affective capacity to share another’s feelings, and (ii) the cognitive ability to understand another person’s feelings and perspective. Sometimes the definition also includes the ability to communicate one’s empathetic feelings and understanding to another person by verbal and/or nonverbal means. Carl Rogers<sup>6</sup> wrote “...the state of empathy or being empathic is to perceive the internal frame of reference of another with accuracy and with the emotional components and means which pertain thereto as if one were the person, but without ever losing the ‘as if’ condition.”

Attention and listening are closely related to one another. They refer to the behavioral skills that by focused listening pay close attention to the patient, limiting distractions, and equalizing the power between the counselor and the patient. As an attentive listener, the STI counselor should try to pick up the patient’s experiences, behavior, feelings, and point of view when talking about his/her experience, behavior, and feelings. The counselor

should also allow the patient to find out his or her own solution if (s)he can. If (s)he needs help, avoid ordering him/her to do things. Give suggestions from which he/she may be able to choose.

There are many different counseling techniques such as open questioning, paraphrasing, reflecting feelings, clarifying, repeating, probes, summarizing, and nondirective approach.

To summarize, an STI counselor is empathic, well-informed, not biased/judgmental/condemning, not emotionally involved (compassionate people should guard against this), authentic/genuine, open-minded; and warm, friendly, calm, patient, understanding, flexible, and creative. It is important to remember that STI knowledge, self-awareness, and developing counseling skills and techniques are an ongoing process and our competence as counselors can always improve and be refined.

## THE AIM OF STI/HIV COUNSELING

The overall aim of STI counseling is to prevent future occurrences of other STIs for the patient and transmission of the disease to others by initiating a reflective process of developing a realistic risk-reduction plan (if time so permits) or at least inform the patient about safer sex behavior. It is also to help him/her to have a realistic understanding of the STI, and to educate him/her about necessary treatment.

## COUNSELING PROCESS IN STI MANAGEMENT

Probably the most important starting point is for the counselor to give the patient an opportunity to express discomfort and for the counselor to recognize this discomfort. Most patients have usually thought quite a lot about the issues before they consult a counselor and often have arrived at some conclusions about the nature of their problems. STI/HIV counseling is a process divided into pre- and post-test counseling.

## Revealing Details of Sexuality

Sometimes, especially in more stigmatizing contexts or where such behavior may be illegal, patients may not reveal crucial details of their sexuality (e.g., that they have contact with people of the same sex, with commercial sex workers, as a result of incest or sexual assault, or with under-age partners). Such patients are likely to conceal aspects of their sexuality from most people, to expect the most negative social reaction to their sexuality from significant others, society in general, and their health practitioner in particular. Where the practitioner is required by law to report particular behaviors, such nonadmission may be understandable. This has a number of practical applications for counseling. As lack of previous STIs in nonadmitters suggests that the clinic situation will be a new and potentially frightening one, in which condemnation is expected; in subsequent visits to a clinic, the patient will tend to be less apprehensive if the clinician's approach has been nonjudgmental. Thus, the first part of the visit is crucial in building up the rapport that is so critical for taking sexual histories and for sexual counseling. The apparent passivity and

lack of assertion that are also predictors of failure to reveal matters about one's sexuality, suggest that many patients may have trouble expressing what is construed as negative information that may elicit a negative response. It may also be that when counselors take histories in a manner that implies any sexual contact was a heterosexual or homosexual one, or consensual, the patient may not have the courage to make a correction.

However, these psychological factors will clearly operate in interaction with environmental factors such as the clinic, the clinician, and the legal and social climate regarding sexuality. Individual practitioners can do little more than to be aware of the factors operating, and seek to actively mitigate them through their interaction with patients, particularly emphasizing genuineness and empathy as well as specifically dealing with their therapeutic acceptance or what patients may consider shameful or abnormal practices. The imposition of shame and guilt upon sexual interactions by religious and other traditional moralities is the single most important cause of psychological problems in STI treatment, and if the practitioner is able to assess and deal with this early in the treatment process, many difficulties may be prevented or minimized. Lack of consideration may even introduce or reinforce shame or guilt and produce an iatrogenically strengthened distress. A high index of suspicion for psychosocial problems attendant on STI infection or reported infection is mandatory to ensure accuracy in history taking and maximal adherence with treatment, contact tracing or partner notification, prevention and preventive education and the possible contribution of psychosocial factors to relapse or reinfection should not be underestimated. It can, however, be to some extent neutralized by careful, sympathetic, and tactful handling.

## Pre-Test Counseling

Pre-test counseling encompasses informative and preventive components. The informative component refers to addressing the test to be taken and the possible treatments of the condition and possibility of transmitting the condition to others. When the patient actively seeks HIV counseling and testing services (i.e., patient-initiated counseling and testing), the informative component addresses issues such as the desirability and implications of taking an HIV test, the clinical benefits of testing and the potential risks (discrimination, abandonment, etc), as well as its voluntary nature. In all STI counseling, an opportunity should always be provided for the patient to ask the counselor questions.

The preventive component of all STI counseling focuses on the patient's own unique circumstances and risk taking and should help the patient to reflect upon his/her risk behaviors and ways to reduce the risks. However, STI/HIV prevention education varies widely from highly effective interventions to useless imparting of information that leaves the patient confused and feeling trivialized. Just providing a pamphlet or launching into condom directions use is insufficient for most people to modify their behavior, although written materials should certainly

be provided as background and back-up information. Help the patient to identify risk factors and cofactors: When are you most at risk for engaging in unsafe sex? What things make it more likely for you not to use a condom? Focus on behavior patterns. While some patients may prefer to see an STI or HIV as a “freak” occurrence, for example the monogamous wife infected by her husband’s extramarital contacts, other STIs occur following a *pattern* of risk behavior. Work with the patient to develop an individualized plan to prevent further STIs if this latter scenario is the case. For example, if a patient is more likely to engage in unprotected sex when feeling depressed, ask the person to identify early signs of depression for her or him, and then work together on solving the problem. What specific situations for the future are of most concern? In developing an individual plan, keep in mind that small changes in behavior are more manageable and successful than total lifestyle changes.

Just telling a patient to use condoms is not sufficient. If patients report a dislike of using condoms, work with them to identify the reasons they don’t use them, then develop a realistic plan for introducing condom use into future sexual activity. For example, if a man complains that he has decreased sensitivity when using condoms, you can suggest putting some lubricant inside the tip, or partners using the “female” condom. A couple who don’t use condoms because they are married or “in love” can be encouraged to examine the idea that part of loving is looking after one’s own and one’s partner’s health. The man who fears erectile failure or inability to ejaculate when using condoms can be assisted by reframing the problem to focus specifically on these concerns. While most sexually active patients have experimented with condoms at least once, some patients may report never having used condoms. In these cases, demonstrating condom use in the counselor’s office is most effective. In particular, having the patient handle the condom and practice putting it on by demonstrating on two of their fingers increases the chance of future use. Consider referral for follow-up counseling as appropriate.

A helpful insight is to view risk behavior both as a problem in itself and as possibly symptomatic of other underlying concerns. Studies in HIV prevention have identified many cofactors of risk including concurrent drug/alcohol use, depression, and other mental health concerns; sexual anxiety; history of sexual abuse; lack of assertiveness; and in some contexts, sexual orientation.<sup>3</sup>

Counselors need to be flexible with regard to what extent the preventive component should be at focus when conducting pre-test counseling. It should also be noted that the patient is entitled to refuse receiving counseling in any form. If a disease is notifiable to a government department, especially by name or other identifying details, this should also be disclosed.

## Post-Test Counseling

During the post-test counseling session the patient is notified about his/her STI/HIV test result. The session includes care/support, informative, and preventive aspects.

## Care/Support Aspect

For patients being notified of an STI diagnosis, they should be provided comprehensive and thorough care encompassing medical treatment and if needed psychological care to reduce psychological sequelae of the STI diagnosis. Appropriate referral when needed should also be provided. It is not uncommon that patients being diagnosed with an STI may experience feelings of being “punished” for sexual activity, loss of self-esteem because of the contraction of an, from their point of view, unacceptable disease. It may also have effects on the primary relationship in making spouse or partner aware that their partner has had sexual contact outside their relationship. This latter result of an STI may itself include sequelae such as relationship breakdown, depression or anxiety, or severe or dysfunctional guilt.

Along with the potential psychological sequelae, it is important to note that any STI diagnosis may have sexual sequelae. For some recurrent STIs, such as genital herpes as well as HIV infection, there are also recurrent sexual problems that need to be dealt with.<sup>3,7</sup> While the sexual problems are less well-documented and defined, several patterns exist. For many, possibly most, patients they experience a loss of sexual desire and even sexual functioning in conjunction with the diagnosis. They describe their sexual desire as having left them and the length of the “lost sexuality” differs between patients. While many patients may not be sexual with others, they may begin through masturbation to adjust sexually. Some men and women describe relating to their semen and vaginal fluids in a new way, seeing them as dirty and dangerous, symbolic of the disease that infected them. Eventually the person’s sexuality and sexual behavior patterns start and may return to the levels existing prior to diagnosis, with the exception that safer sex for many people takes on a new importance. MSM diagnosed with HIV quite often select other HIV-positive persons (i.e. “serosorting”) as sex partner, often via the Internet or organizations for people living with HIV.

It is helpful for counselors to view sexual activity as part of a person’s wider perspectives on life and adaptations. Whether through masturbation, sex with a significant other, or casual sexual activity, most people find sex to be powerfully releasing, distracting, grounding, affirming, and/or reassuring. Focusing on sex as a “problem” is not only counter to most people’s experience of sex, but may limit the credibility of the counselor as a source of advice, casting them instead as a moral agent or authority. People undergoing profound stress, including the newly diagnosed, may also use sex to cope with the stress (both functionally and dysfunctionally). A small minority of newly diagnosed persons with HIV may binge sexually following diagnosis. While some authors have suggested that this is an angry retribution reaction, in our experience it occurs primarily in persons with a history of compulsive sexual behavior and may more accurately and simply be defined as a person having a “slip-up” into a previous behavioral pattern. When testing for HIV, asking patients how they have coped with previous stressors and taking a good sexual history will clearly be helpful, as these may predict and prevent such behavior.

### Informative Aspect

Given the meanings of STIs discussed above, it is important to understand what having an STI means to the patient. In counseling, the aim should be to assist the patient to gain a realistic understanding: not so pathologized that the patient suffers significant psychological harm, nor so trivialized that the patient dismisses the infection as unimportant. In most cases, the patient is likely to overpathologize; hence it is important to balance this tendency with reassuring information. In some cases, particularly where the person feared the symptoms were those of HIV, diagnosis with a (non-HIV) STI may actually be a relief to the patient. Therefore, it is important to ask the patient how he or she feels and what they are thinking following diagnosis. Providing written or easy-to-understand information on the particular STI is important. Normalizing feelings of guilt and shame as transient reactions following an STI can also be helpful. For STIs that are likely to be recurrent (e.g., herpes) or chronic (e.g., HIV disease), the counselor should spend time reviewing what signs and symptoms a patient should note, and that infectivity may occur without signs or symptoms. In particular, patients need specific direction on when they can resume sexual activity, and when condoms must be used.

Another informative aspect is related to STI treatment. Obviously, this will vary according to the specific STI(s) diagnosed. Particularly in cross-cultural settings and settings where language is a barrier, it is important to ensure instructions are clearly understood. When providing oral medication, for example, ensure that the patient knows to take the medication orally, not as a suppository. Ensure that medication is taken under appropriate conditions (liquid, food, timing), and particularly, that antibiotic courses are completed or antiretroviral treatment (ART) is taken regularly to keep the viral load undetectable and to prevent development of drug-resistant strains. Asking the patient to repeat back to you any medication instructions can clarify the patient's understanding.

### Preventive Aspect

This aspect refers to behavioral changes (individual level) and STI disclosure to sex partner (interpersonal level). It is important to address unsafe sex patterns, particularly with persons living with HIV. Rather than giving advice – “you must always practice safer sex” – it is more helpful for the health professional to establish a relationship where both practitioner and patient can raise safer-sex concerns. Rosser et al.<sup>8</sup> in a recent study of 106 HIV positive persons found that one in four HIV positive persons admitted having unprotected sex with HIV negative or HIV status unknown persons post-diagnosis, and 10% believed they had infected others post-diagnosis. HIV positive persons having unsafe sex did not differ from positives who maintained safer sex—both knew the rules and had experience with safer sex. Hence, providing safer-sex education is not sufficient; one must specifically address the unsafe sex. The goal of such counseling should be to promote the sexual well-being of the patient: first,

by assisting the patient to recognize his or her risk behavior patterns, antecedents, and cofactors; and second, by addressing these patterns through counseling, treatment, and referral. It is also important that counselors address the window period and risk reduction strategies with patients receiving an HIV negative test result.

The other component of the preventive aspect is disclosure to sex partner of one's STI to prevent patient reinfection and to prevent further spread of the particular disease. Patients can themselves tell current or future partners about their STI/HIV or inform their partner(s) through partner notification. However, partner notification is to many patients a sensitive area and needs careful explanation as patients are often initially reluctant to contact partners. Where both partners are being simultaneously treated by the practitioner, relationship counseling may often need to occur as a function of one patient blaming the other for the STI or because the exposure of outside sexual contact leads to strains in the relationship.

Many patients perceive STI disclosure as stressful, which should not be underestimated. Without summarizing in detail the many issues that STI may elicit or precipitate, it is important to note two points. First, the counselor might be the only individual with whom the patient will be able to discuss the infection (and thus fulfils an important role as a supportive listener for a wide range of conflicts and concerns). Second, as already noted, the stigmatization surrounding HIV and some other STIs may precipitate a number of dysphoric mood states, or identity or relationship crises, which require just as much in the way of identification and management as will the infection itself. Great care should be taken to avoid recommending disclosure that may exacerbate the patient's situation and lead to serious discrimination or threats to life or livelihood. Obviously, balancing disclosure and threat of discrimination must be tailored to each individual case and carefully weighed. Such decisions need to be made by the fully informed patient, not the counselor!

### Staging of Reactions to HIV and AIDS

The emotional impact of HIV infection appears to be qualitatively and quantitatively different from that of curable STIs.<sup>9</sup> A diagnosis of herpes may be assumed to have a similar, if lesser, impact, given that the disease is incurable, if not life-threatening.

There are stages of response to the diagnosis through which individuals may pass. In many ways, these stages are similar to those described by Elizabeth Kübler-Ross<sup>10</sup> in her description of patterns seen when a person is coming to terms with a diagnosis of terminal illness. They do, however, differ in some important respects since the trauma may include stigmatization as well as the possibility of death. Ross et al.<sup>11</sup> have described the reactions of homosexual men to asymptomatic HIV infection. They note that HIV infection may not lead to death, and hence the Kübler-Ross<sup>10</sup> model of response to a terminal diagnosis may not always be appropriate. The stages bear some similarities to models of homosexual identity formation. This is to be expected. Firstly,

there is considerable stigma attached to infection with HIV or herpes and the stigmatized status is not usually visible or identifiable. Secondly, a significant proportion of individuals carrying antibodies to HIV in the western world are homosexual or bisexual men. In many cases they will use a previously appropriate and successful coping strategy to manage a second stigmatized status. The authors note that individuals may show retrogression as well as progression between stages: some individuals may neither experience every stage nor go beyond a certain point. It might also be of value for the practitioner to be aware that in close-knit relationships, the patient's partner may pass through these stages in parallel with him or her.

Shock, denial, and anger may be a first reaction to discovery that one is infected with HIV, and this may be exacerbated by stigma associated not only with HIV but also by stereotyping of individuals with HIV as acquiring the infection by being sexually immoral. Helpful responses by the health practitioner are to be quietly supportive and to allow the person to progress at his or her own rate. During the early phases, the person cannot take in much information; therefore it is appropriate to avoid overload. It may not always be helpful to encourage patients to express their emotions, especially in denial or where the emotions are unmanageable. Take your cues from the patient! At this point it can be a good thing to review with the patient a plan of action between this initial session and follow-up (ideally 48–72 hours following diagnosis).

The recognition that one has an HIV infection may lead to withdrawal. This recognition may lead to isolation, either imposed or self-imposed, sexual, or social. Recognition of the stigma associated with infection may activate previously successful coping strategies in groups such as homosexuals and injecting drug users. Individuals at this stage tend to keep to themselves as part of their uncertainty about the reactions of others. In an extended family situation, the reaction of other members of the family may be threatening or rejecting. Other salient factors in the withdrawal may be related to fear of infecting others and to depression. One of the reasons why a follow-up appointment after diagnosis is appropriate is that it allows you to monitor how withdrawn the patient has become. The roles of the practitioner during this phase include monitoring the patient's isolation (and in some circumstances, suicidal ideation) and being a confidante of the patient.

The individual who is positive for HIV antibodies or herpes infection typically discloses the situation to those who are most likely to be accepting, family, or significant others. Psychological processes may include negotiating the need for acceptance, expressing the need still to be loved and displacing stress onto people taken into confidence. The health practitioner's role during this phase includes being a resource for the patient, their family, and their significant others where appropriate. For the newly diagnosed person, the practitioner can assist by being a "safe person" for discussing how to disclose infectious status and to whom. Wherever possible, it is helpful for the practitioner to gently place the question of whom to tell back on the patient,

discussing the pros and cons of disclosure in each individual case. As the patient tells others, he or she may have specific questions about HIV, safety from infection and so forth. Others may need help processing their emotional reactions.

It may also be helpful for the patient to locate other people in a similar situation, looking for the social and psychological support of those with a similar diagnosis. Sharing problems and reactions with those "in the same boat" is a potent source of information, comfort, and coping strategies. Previously the practitioner's role may have been a rather dominant one, journeying with the patient during his or her adjustment. Now the role may be to refer on to support groups. Self-help groups may foster acceptance and provide the patient with skills and confidence to play a more active role in managing the disease. The practitioner's role now includes affirming the patient's developmental process in managing the disease. The desire to help others in a similar situation may be part of the process of "making friends with one's disease" and gives purpose in a life disrupted by the diagnosis and enhances coping. The primary role of the practitioner is to assist the person to make their decisions in freedom, to explore motivations, and as with all health concerns to assist the patient to make decisions that are healthy and realistic. In time, integration of positive HIV status as part of the patient's identity occurs.

These "stages" – while by no means invariable or a regular progression – illustrate that for the same diagnosis, different patients may not only be at different "stages" but may also progress (or regress) and be dealing with different psychological issues at different times. While no one strategy is appropriate for everyone, for healthy long-term adjustment a patient-empowerment approach is usually recommended. Such an approach views health practitioners as important consultants – part of a team coordinated by an informed patient who is the manager of his or her health. For health practitioners and patients who use such a style, the practitioner–patient relationship is often experienced as powerful, and as part of the best tradition of healthcare. Here, authoritarian, unilateral decision-making by practitioners is inappropriate and potentially harmful, especially where the patient is progressing through stages of coming to terms with the disease and the practitioner is not moving at the same pace. The patient's perceptions of cooperation and care are paramount in their interpretation, even if they do not coincide with the view of the practitioner: the patient will always see their own perspective as the "real" one.

### Sick Role Behaviors in STIs

In the case of individuals with an erroneous conviction that they have an STI, which Hart<sup>12</sup> refers to as venereoneurosis, the person displays both general hypochondriasis and a strong disease conviction without demonstrable evidence of infection. It most commonly occurs in patients who see STI as punishment for some real or imagined misdeed, usually of a sexual nature. The attention given to HIV infection has made "AIDS phobias" a clinical phenomenon. The individuals presenting with the phobia are usually concerned over sexual contact outside primary

relationships and are experiencing stress at work or in relationships, which often acts as a trigger. Ross<sup>3,13</sup> has suggested that when such patients are provided with insight into the additional factors that have led them to present with their concern at this time, the issue of HIV infection will often drop away and the other concerns (guilt over sexual behavior or outside sexual relationships for which the possibility of HIV infection is “punishment”) will emerge. There may also be an indication that the patient believes he or she “deserve” the infection. Brief insight-oriented counseling is the treatment of choice provided there is no evidence of psychosis. It is important not to perform repeated HIV testing, which may only reinforce the patient’s conviction of infection. Paradoxical interventions have been suggested as appropriate to psychotherapy for people with intractable HIV worry, but these interventions (which involve treating individuals as if they were infected in order to release them from their rigid and distressing beliefs) should be carried out only by competent psychotherapists.

Illness behavior refers to how a person responds to illness. In the case of most sickness, there may be a “sick role” associated with the condition and people may receive support and comfort from others (referred to as secondary gain). However, for stigmatized conditions, there may be no illness-related behavior because not only would there be no secondary gain, but secondary loss. It is thus not surprising that sick role behaviors in STIs do not occur as they do with most other medical conditions. The reaction of individuals – which is perhaps most commonly found – is a refusal to see STI as an illness; rather, it may be regarded only as a minor nonsignificant risk of a particular lifestyle. Clinical observation has tended to suggest that in the case of the absence of illness behavior, patients may frequently compromise treatment: by discontinuing medication after symptoms have resolved; by continuing sexual activity after symptom resolution but before clearance; or by not returning for proof of cure. Thus, both abnormal illness behavior such as disease phobias and lack of normal sick role or illness behavior may have implications for the management of STIs.<sup>14</sup> Compared with other illness behaviors, in which there may be substantial secondary gain from sympathy and assistance, STI infection appears to be quite different and to develop as a function of repeated infections. In such cases, would appear that STI infection tends to be seen as a chance event until several infections have occurred, when it is then seen not only as an illness<sup>12</sup> but also as a result of particular behaviors. It has been noted, using non-STI controls attending general practice and psychiatric outpatient clinics, that the STI clinic population is closer to the psychiatric population than the general practice one. This is consistent with the finding of Catalan et al.<sup>15</sup> that 40% of a United Kingdom STI clinic population had some degree of psychological disturbance on a screening test. It is unclear whether the disturbance was a function of having a stigmatized illness such as an STI or inherent in STI clinic attenders. There may be major differences between public and private clinics, and between the accuracy of histories at STI clinics, depending on individual factors such as practitioner approach and clinic environment.

## Conclusion

Psychological aspects of STIs play a central part in understanding the incidence, presentation, treatment, and prevention of these diseases. This is particularly true where the infection is not curable or is associated with stigmatization (e.g., HIV infection). In sexual counseling within the context of managing STIs, the psychological aspects of the problem may cause as much or more morbidity and distress as the physical ones, and these reactions need to be understood and treated by the counselor. Understanding some of the ramifications of STIs (including HIV infection) that are described in this chapter, as well as some of the counseling approaches to them, should place the counselor in a good position to deal with them in clinical practice. The goals of counseling should include accuracy in history taking and treatment, and promoting the sexual wellbeing of persons with STIs/HIV and the communities and networks within which they make their sexual contacts.

# Role of Behavioral Interventions in Prevention and Control of Sexually Transmitted Infections and HIV

Devinder Mohan Thappa • Amiya Kumar Nath

# 10

Human behavior is the result of the complex interactions of physical and mental factors.<sup>1</sup> All forms of behavior are responses to stimuli like environmental stimuli, emotion and feelings, needs, motivation, and intellectual perceptions. Moreover, behavior is also described as an adjustment to meet the need of a given situation. Behaviors of an individual or communities are influenced by factors such as knowledge, beliefs, values, attitudes, skills, finance, materials, time, and also by the influence of other members of the society like family members, friends, coworkers, opinion leaders, and health workers. Pervasive issues like prevailing norms, male/female roles, ethnic discrimination, poverty, unemployment, and educational opportunities may limit the ability of a certain section of the society to behave in a healthy manner. Health behavior refers to those activities which people undertake to avoid disease and the efforts they make to facilitate the detection of asymptomatic infections through appropriate screening tests. Illness behavior refers to how people react to symptoms, and how quickly they seek help (medical or otherwise). Treatment behavior refers to those activities used to cure diseases like taking adequate medication, reporting for follow-up, etc.<sup>1</sup>

The means of sexual expression are infinitely greater than those that are acknowledged or sanctioned by the defined legal and moral systems of most societies which either openly or clandestinely provide opportunities for varied sexual expressions. Sexual behavior typically does not occur in public, making it difficult to motivate protection when potential transmission occurs.<sup>2</sup> Factors related to STI-associated risk behaviors are dependent on various aspects of individual characteristics like his/her social interactions and characteristics of the school, community, and society<sup>3</sup> with which they are associated.<sup>3</sup> Factors like family support, which include upbringing of the offspring, parent-child interaction and parental influence, and monitoring relationship characteristics, such as lack of relationship control, longer length of relationship, fear of condom use negotiation, less frequent partner communication about sexually related topics, and having older sexual partners, have been associated with greater likelihood of engaging in risk behaviors or acquiring sexually transmitted infections (STIs). Additionally date rape,

new partner and risky partner, peer influences and peer pressure to smoke, drink alcohol and engage in sexual intercourse also play a vital role. Social capital (an index comprised of trust, reciprocity, and cooperation among members of a social network) is inversely correlated with HIV/STIs acquisitions. Various aspects of community largely affect adolescent risk of STI acquisition. Communities that have high rates of STIs among adults may pose a heightened risk for adolescents. Sociological factors like poverty, low educational attainment, compromised family structures, and lower socioeconomic status are also important. The media and pornography indirectly have an important influence on the sexual health of adolescents. Adolescents may engage in risky sex or non-use of condoms due to lower level of perception of the risk for pregnancy and STIs. Multiple partners, lack of confidence in using condoms, inability to negotiate condom use with their partners, inability to say “no” to sexual intercourse not protected by a condom, belief that using condoms results in less pleasure, perception of low susceptibility to STI and HIV infection, inability to discuss sexual matters (i.e., previous partners, sexual histories), and current pregnancy all lead to a high risk of acquiring STIs. Psychological parameters like high levels of impulsivity, proclivity for sensation seeking behavior, alcohol or drug use, antisocial behaviors, low self-esteem, psychological distress, and depression further multiply the risk of acquiring STI in the adolescents. The shift toward later marriage in most countries has led to an increase in premarital sex, the prevalence of which is generally higher in developed countries than in the developing countries, and is higher in men than in women.<sup>4</sup> Sexual behaviors and the sharing of injection equipment that cause most HIV infections worldwide occur for many indulging motivations like desire, peer pressure, pleasure, physical or psychological dependence, self-esteem, love, access to material goods, obligation, coercion and force, habit, gender roles, custom, and culture.<sup>2</sup>

Advances in scaling up antiretroviral treatment in resource-poor countries, the benefits of male circumcision, and the hope for promise of pre-exposure prophylaxis and microbicides have made some difference; however, there is no simplistic solution to HIV prevention.

Behavioral interventions in HIV/STD prevention are a subject of considerable interest and debate. Two and a half decades ago no one would have thought that HIV prevention would be as difficult as it has proven to be. Despite efforts, UNAIDS now estimates that 33 million people are living with HIV, and 2.5 million new infections arise every year.<sup>2</sup> In the absence of effective vaccines behavioral interventions are the key to HIV/STD control strategies, but the question of what actually works remains a challenging one.<sup>5</sup> While biological science continues to unravel the secrets of the HIV, behavioral science has contributed much to our understanding of its prevalence, incidence, and distribution.<sup>6</sup> In the USA, studies on homosexual men show rapid reductions in high-risk behaviors and falling incidence of infectious diseases, including HIV, as the result of public health interventions.<sup>7-10</sup>

Dynamically changing demographic, economic, and cultural forces underlie the behaviors that directly determine the spread of STDs.<sup>11</sup> In many developing countries, additional social problems such as rapid population growth, rural to urban migration, work related travel, growing economic inequality between the rich and poor, low education and low status of women, political instability and wars all result in behaviors that fuel the hyperendemic transmission of STIs, with continuing epidemic spread of the newest STIs and HIV infection. Sociodemographic data and ethnographic research suggest progressive liberalization of sexual behavior during the 19th and 20th centuries, as a result of colonial and economic development, urbanization, population growth, and other factors.<sup>12,13</sup> Many societies especially developing countries however are still reluctant to openly address issues involving sex and sexuality and to recognize the realities of the widespread existence of pre- and extramarital intercourse.<sup>14</sup> This narrow minded attitude best explains the subsequent epidemic spread of HIV and other STIs.<sup>15</sup>

The HIV epidemic has been the single most important factor to both highlight the need for more systematic dissemination of information on sexual behavior and facilitate an enormous increase in infection related studies on sexual behavior.<sup>11</sup> It is now clearer than ever that sexual behavior is one of the most complex human social behaviors.<sup>16,17</sup> The term “sexual behavior” involves many components: sexual experience and activity, age at sexual debut or “coitarche”, current and life time number of sex partners, frequency of sexual intercourse, mode of recruitment of sexual partners, duration of sexual unions, and types of sexual practices.<sup>18</sup>

In a vast country like India, there are wide variations in geographical, cultural, and behavioral patterns.<sup>19</sup> Variations in sexual behavior patterns, even within a population influence the spread of STIs in that population. Linkages between sexual networks are necessary for the spread of STIs across these networks.<sup>20</sup> So called “core group” appears to be important in the spread of STIs and in their prevention. Core group refers to a small proportion of persons with an STI who transmit the disease, e.g., commercial sex workers (CSWs) and who sustain the endemic and epidemic transmission of STIs. Mixing between members of the “core” and the “periphery” affect the extent to which STIs spread to the general population. The sexual

transmission of STIs and HIV beyond core groups depends on persons who have sexual intercourse with members of the core group and then also with members of the general population and are called “bridge population”. Studies in Thailand revealed that large proportions of men in certain occupations such as truck drivers, the police, and the military tend to function as “bridges” between female sex workers and their wives or girl friends.<sup>21,22</sup> This pattern is observed in other diverse settings, particularly in Asia. In India, a high proportion of HIV positive persons are truck drivers who generally, acquire the infection from CSWs doing business on the highways leading to Mumbai or Chennai, 2 metropolitan cities of the Western and Southern zones of India, respectively. These long distance truck drivers through their high-risk sexual behavior contribute to the rapid spread of HIV infection. The transmission dynamics of STIs are influenced not only by sexual behavior but also by additional factors such as phase of the epidemic, population prevalence, transmission probability, duration of infectiousness, and specific characteristics of transmission networks.<sup>23,24</sup>

## What is Meant by Behavior?

Behavior is everything we think, do, and feel. It is not something, we are born with. We are born with temperament, physical, and sexual characteristics and these interact with our environment to produce our behavior and our habits. Behaviors take place over and over again until they become automatic and take place without the person having to think a great deal.<sup>25</sup>

Behavior is formed by a combination of 8 different factors: (1) The body and temperament we are born with which includes factors like intelligence, general health, physical appearance, handicaps, disabilities, talents, etc. (2) Gender which has an impact on what he or she does and what they are able to change, e.g., economic constraints on women, different values for male and female sexuality, powerlessness of woman relative to man, etc. (3) Culture greatly influences as particular cultural practices may help or hinder the patient’s ability to change, e.g., polygamous marriages, wife inheritance, rituals, cultural practices, and values about marriages, sexuality, child rearing, etc. (4) Religion plays an important role as the extent to which the patient’s religious beliefs help or hinder their attempts to change their behavior. (5) Economic conditions are vital as they help us understand whether the patient has ability to earn or have access to what he/she needs for survival. Do they have economic freedom to look ahead or make plans for the future? Do they have the economic resources for adequate healthcare and information? (6) Family and community which help shape the values, beliefs, and circumstances of patient’s social environment, and include friends, family, and sexual partners. Does the social environment offer support and assistance? Is the patient ostracized from his/her social environment because of his/her behavior? (7) Physical environment which helps determine whether the patient has adequate food, clothing, shelter, and water. How many people live in the same home? Under what circumstances? Is the area safe? (8) Personal factors like what are the personal resources or

weaknesses of the patient? Is the patient depressed, lonely, angry, or feeling overwhelmed? Does the patient have problem with drug or alcohol abuse?<sup>25</sup>

### What is Meant by Behavioral Intervention?

Various terms, including behavioral, psychosocial, and life style are used to describe very different kinds of interventions designed to change a wide range of human behaviors.<sup>5</sup> For example, the intervention may range from a brief exchange of information or advice to long term intensive psychological “counseling” or therapy. The aim of behavioral intervention may be to change behavioral patterns like smoking, exercise, dietary patterns or sexual behavior of individual(s), small “high risk” groups, or of communities as a whole. In the context of HIV/STIs prevention, a behavioral intervention is one that seeks to reduce the risk of acquiring or passing on HIV or other STIs by changing behaviors that lead to transmission of infection, principally sexual and injecting behaviors. This still encompasses a wide range of possibilities, even though the link between behavior change and transmission of infection may be fairly direct (for example, consistent use of condoms between known HIV discordant sexual partners) or much more direct (for example, raising self-esteem or negotiation skills among sexually inexperienced young people to reduce the likelihood of high-risk sexual behavior in the future).

National AIDS Control Organisation (NACO) has also recognized the role of educational and behavioral interventions. The 2nd National AIDS Control Program (AIDS II Project) has shifted its focus from raising awareness towards changing behavior through interventions, particularly for groups at high risk of contracting HIV.<sup>26</sup> Strategic plan gives primary importance to components of Information, Education and Communication (IEC). Information means news, data, facts, or knowledge. Education is the process by which people acquire knowledge, skills, habits, values, or attitudes. The word education is also used to describe the results of the educational process. Communication is sharing/providing information by speaking, writing, or other methods. It could be verbal (one way or two way) or nonverbal (body language—gestures, dress, behavior, eye to eye contact, facial expressions, messages on flip chart, flannel graphs, posters, billboards, flash cards, etc.). Probably, the most important type of communication is interpersonal or person-to-person communication, which happens when people make their thoughts and wishes known to one another. To sum up, IEC is a process that informs, motivates, and helps people to adopt and maintain healthy practices and life styles.<sup>25</sup>

### OBJECTIVES OF BEHAVIORAL INTERVENTIONS IN PREVENTION OF HIV/STIs

Goals for behavioral strategy involve spreading of knowledge, stigma reduction, access to services, delay to first intercourse, decrease in number of sexual partners, increases in condom use, and decrease in sharing of contaminated injection equipment.<sup>2</sup>

Although, sexual abstinence is a desirable objective,<sup>27</sup> programs must include instructions on safer sexual behaviors like<sup>14,27</sup>

1. reduction in the number of sexual partners,
2. avoidance of risky sexual practices,
3. where indicated, the consistent use of barrier methods such as condoms, and
4. a change towards appropriate healthcare seeking behavior, where infection is suspected.

Emerging risk groups such as young people, CSWs, mobile population and women (in whom the transmission of HIV virus to their children remains a major public health problem) should be targeted with behavioral interventions.

### STRATEGIES AND ACTIVITIES OF IEC<sup>26</sup> COMPONENT OF NATIONAL AIDS CONTROL PROGRAM

1. To raise awareness, knowledge, and understanding among the general population about AIDS and HIV infection, its transmission and methods of prevention.
2. To promote safe practices such as condom use, use of sterilized needles and syringes, use of safe blood through promotion of voluntary blood donation.
3. To mobilize all segments of the society to integrate AIDS messages and programing into existing activities.
4. To ensure that all relevant health workers are trained in AIDS communication and coping strategies.

It is now well-recognized by the authorities that the IEC activities in isolation are not effective. Therefore, the IEC has been integrated with the other components of the AIDS Control Program. Condom programing, STD services, and blood safety program carried out by well-trained health personnel, back the educational messages and information.

### BASIS OF BEHAVIORAL INTERVENTIONS

Behavioral interventions have been based on a number of psychological models such as theories of reasoned action,<sup>28</sup> self-efficacy,<sup>29</sup> and readiness to change.<sup>30</sup> Even though every behavior is unique, theories of behavioral prediction and behavior change suggest that there are only a limited number of critical factors (or variables) underlying an individual decision to perform or not perform a given behavior.<sup>31</sup> Behavioral science theories and research also suggest that the most effective intervention will be those which are directed at a specific behavior. Perhaps the most difficult part of developing any intervention is the identification of the behavior (or behaviors) that one wishes to change. The selection of a behavior (or behaviors) to serve as the target of an STI/HIV risk reduction intervention for a given individual, should be based on sound epidemiological evidence and a careful assessment of client's sexual and drug use history.<sup>32–36</sup> It is only by knowing the history that one can identify the one or two behaviors that are putting the client at greater risk for acquiring and transmitting HIV and other STIs. This behavior (or these behaviors) should serve as the target of an intervention.

Behavior change is usually not a one-step, all or nothing process but often involves a series of steps that ultimately may lead to long-term maintenance of a new behavior. Clearly, different behavior change messages will be necessary for a person who has not even thought about adopting a health-protective behavior than for a person who is trying to adopt that behavior.<sup>30,37,38</sup> By understanding the client's behavioral attitude, normative (patient's perceptions of what others think he/she should do), self-efficacy (patient's self-perceived ability to perform a target behavior), and beliefs, it should be possible to tailor a theoretically appropriate intervention.<sup>39</sup> Carefully designed theory based interventions that take into account the characteristics of the particular population or culture can cause positive changes towards preventing sexually risky behaviors but boundary conditions for their effectiveness still need to be identified.<sup>40</sup> Unfortunately, such theoretical considerations are often not taken into account in developing interventions.<sup>31</sup>

It is important to recognize that behaviors, even those which have been viewed as difficult or impossible to change (for example, sexual and drug using behaviors) can be changed and changed radically.<sup>31</sup> Moreover, it is also important to recognize that there are only a limited number of theoretical variables that influence and account for most of the variance in any given behavior. Generally speaking, once a person has formed a strong intention (or made a commitment) to perform a particular behavior, he or she is likely to perform that behavior given that the person has necessary skills and there are no environmental constraints to prevent behavioral performance. If not so, the healthcare provider can then determine whether failure to engage in protective behavior recurred due to lack of intention, lack of skills, or due to the presence of environmental constraints. If the failure is due to lack of intention, the provider can rapidly assess the client's behavioral, normative, and efficacy levels. Discussion of these beliefs along with the establishment of a risk reduction plan should help the client to change his or her behavior, thus reducing incidence of STIs.

### MATHEMATICAL MODELS IN THE ASSESSMENT OF THE IMPACT OF BEHAVIOR CHANGE

To better understand the role of behavior change and STI prevention as factors influencing HIV seroconversion, consider May and Anderson's<sup>41</sup> model of the reproductive rate of STIs. This model includes an equation for HIV:  $R_0 = \beta cD$ , where  $R_0$  indicates the reproductive rate of infection, typically interpreted as the expected total number of secondary infections arising from a single primary infection early in the epidemic when virtually, all individuals are susceptible.<sup>42</sup> When the reproductive rate is greater than one, the epidemic is growing; when  $R_0$  is less than one, the epidemic is dying out; and when  $R_0$  equals one the epidemic is in a state of equilibrium. Beta ( $\beta$ ) indicates transmission efficiency, or the ease with which an infected person can transmit the disease to an uninfected partner;  $c$  indicates the rate of partner change; and  $D$  indicates the length of time

a person is infectious.<sup>41–43</sup> Each of the parameters on the right side of the equation can be influenced by behavior or behavior change. For example, transmission efficiency ( $\beta$ ) can be reduced by increasing consistent and correct condom use or by delaying the onset of sexual activity; the rate of partner change ( $c$ ) can be influenced by decreasing the number of partners; and the length of time, a person is infectious ( $D$ ) can be influenced by increasing the likelihood that one will seek care at the first sign of symptoms. Biomedical interventions can influence transmission efficiency ( $\beta$ ) and the infectiousness ( $D$ ), whether one takes a biomedical or behavioral approach the impact of a change in any one parameter on the reproductive rate will depend on the values of other two parameters.<sup>41</sup> To complicate matters further, it must also be recognized that changes in one parameter may directly or indirectly influence one of the other parameters.<sup>43</sup> For example, some have argued that an intervention program that successfully increased condom use could also lead to an increase in number of partners, perhaps because now one felt safer. If this were the case, an increase in condom use or a reduced prevalence of STIs would not necessarily lead to a decrease in the reproductive rate. Condom use behaviors are very different with partners perceived as "safe" than partners perceived as "risky". Thus one should not expect to find a simple correlation between decreases in transmission efficiency and reductions in HIV seroconversion. Moreover, it should be recognized that many factors may influence transmission efficiency (e.g., degree of infectivity of the donor, characteristics of the host, type and frequency of sexual practices) and the variations in these factors will also influence the nature of a relationship between decreased STI rates, increased condom use and HIV seroincidence.<sup>44,45</sup>

These conclusions follow from other models of HIV transmission. For example, consider Reiss and Leik's<sup>46</sup> model of the probability of being infected with HIV.

$$p = 1 - [1 - \pi + \pi(1 - \phi\alpha)^{n/s}]^s$$

Where  $\pi$  indicates prevalence,  $\alpha$  indicates infectivity,  $\phi$  indicates condom failure probability,  $n$  indicates number of sex acts, and  $s$  indicates number of partners. Condom use is built directly into this model; moreover, the impact of condom use will depend on the degree of infectivity, the prevalence of the disease in the population, the number and type of sex acts, and the number of partners.<sup>43</sup>

Although this model, like the model proposed by May and Anderson,<sup>41</sup> clearly indicates that there is no reason to expect a simple relationship between a behavior change and reproductive rate of HIV, both models make different predictions about the effect of a behavior change.<sup>43</sup> Both behavior change and STI control can, under certain circumstances, help to reduce the transmission of HIV and other STIs. Although correct and consistent condom use can prevent HIV, gonorrhea, syphilis, and probably chlamydia, condoms are less effective in interrupting transmission of herpes and genital warts.<sup>47</sup> Thus, although one is always better off when using a condom than not using it, the impact of condom use is expected to vary with disease.<sup>43</sup>

## Approaches in Behavioral Intervention and Need to Develop STI Care Facilities

Population of the developing world have only limited awareness of the seriousness of STIs and of their signs and symptoms. Mass media can be used to raise general awareness, but a combination of mass media and interpersonal communication with approaches to modify community norms and provide supportive services, seems most promising to maintain safe behavior or to prevent and change behavior which is unsafe.<sup>48</sup> In addition, there is a need for sustained health promotion programs and education strategies targeted at specific groups which are at an increased risk of acquiring STIs. The content of health promotion messages should be appropriate and in general, options should be offered.<sup>14</sup> For young adolescents, for instance, the message could be to abstain from sexual intercourse until one is in a stable relationship or to explore nonpenetrative forms of intercourse; however, whenever penetrative sex takes place condoms should be used. Male condoms are undoubtedly effective in blocking HIV transmission, but female-initiated methods including physical barriers and topical antimicrobials (vaginal microbicides) need to be promoted because women and young girls account for most of those infected cases in countries where HIV is most prevalent.<sup>49</sup> Examples of specific groups that should be targeted with health education and health promotion approaches are STI patients and their clients, long distance truck drivers, street children, adolescents, and students. NACO has also adopted targeted intervention approach. These include special IEC approaches and provision of support services such as providing condoms and STI services. Some identified targeted population groups are injective drug users, migrant workers, industrial workers, military personnel, the commercial sex industry, street children, truck drivers, and slum dwellers. Educational interventions are useful tools for increasing knowledge and improving attitudes towards HIV infection. Secondary schools are equipped with the best environment for this purpose.<sup>50</sup> It is becoming necessary to carry out interventions among younger groups, as a greater impact is achieved.

Although proper medical treatment and providing adequate psychological and social support to adolescents who are already infected constitute an important aspect of the care, the solution lies in altering the behavior and practices that lead to the acquisition of these infections.<sup>51</sup> Under the auspices of NACO,<sup>26</sup> the Department of Youth Affairs and Sports, Ministry of Human Resources Development has taken up a number of activities to protect youth and to involve them actively in the AIDS prevention and control activities. These activities among youth are being implemented through a program named Universities Talk AIDS (UTA) by National Service Scheme. It is projected to reach all major universities and plus 2 level schools. In order to reach the rural areas, the department of Youth Affairs and Sports has organized many multimedia workshops using rural art forms. Plans are underway to tap large networks of youths like NCC (National Cadet Corps), YMCA (Young Men Christian Association), and YWCA (Young Women Christian Association),

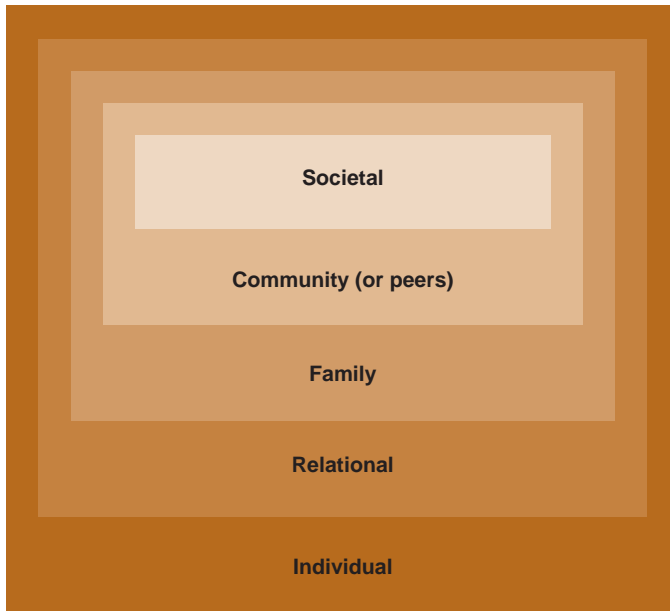

etc. It is also important that the necessary conditions are created for people to take the desired steps to prevent and control STIs.<sup>14</sup> For instance, where condoms are promoted for the prevention of STIs and HIV, good quality, affordable condoms should be readily available and where appropriate healthcare seeking behavior is promoted, good quality, effective, and acceptable services should be available to people with STIs. In developing countries, patients with STIs preferentially seek care in the informal sector for many reasons.<sup>52</sup> The major factor is cost, because the cost of care in the formal private sector is often prohibitive thus the informal private sector may be the only recourse that is open to them.<sup>53–55</sup> Inconvenient hours of operation, long waiting time and concerns about confidentiality and stigmatization all mitigate against seeking care in public clinics. Increased role of pharmacists and informal sector practitioners is being argued by some people, in the provision of STIs care.<sup>53</sup> Patients with STIs prefer the services provided by the informal sector not because these providers offer superior clinical treatment, but because they are accessible, provide medication (even if not efficacious) and involve no waiting time or judgemental treatment.<sup>52</sup> Improving the quality of STI services in the public sector is thus warranted. It is seen that number of STI cases attending STI clinics in government run hospitals are dwindling, however, HIV prevalence is increasing. This shows that attention needs to be given to this health field. In WP Kinsella's novel "Shoeless Joe", the building of an attractive base ball facility was sufficient to cause professionals and general public to flock to it ("If you build it, they will come"), however, this is not sufficient for STI services. Perhaps, the mantra should read, "If you build it and offer high quality, accessible, affordable, and nonstigmatizing STI care services, they will come".

### LEVELS OF INTERVENTIONS<sup>3</sup>

Although many individual-level interventions are effective, they may not be sufficient to sustain newly adopted STI-preventive behavioral changes over protracted periods of time or in the presence of countervailing influences. Effective interventions for behavioral modifications for the prevention of HIV and STIs can be delivered at multiple levels as discussed below (Fig. 10.1).

- **Individual level:** Emphasize motivational factors, provide skills training, including partner communication, sexual negotiation, resistance skills and condom application; and attempt to modify peer norms. Encourage greater participation in screening programs to identify particularly those who are asymptomatic.
- **Relationship level:** This is particularly important for adolescent females who are in power-imbalanced relationships with their male partners. "Adolescent-friendly" partner services represent an approach that may facilitate disclosure and promote care-seeking behavior of partners.
- **Family level:** Promote increased communication between adolescents and parents about STI prevention, increase parental monitoring of adolescents and perceptions of the adolescents regarding enhanced parental monitoring, foster a sense of increased family support.

**Fig. 10.1:** A socioecological model for STI risk and protective factors for adolescents.<sup>3</sup>

- **Community level:** Create social norms that promote safer sex practices. By evoking changes within the community in which adolescents are embedded, STI-preventive behaviors may be magnified. Effective use of adolescents' sexual networks as a venue for preventing and controlling STIs may become productive in the long run. Promoting, enhancing, or creating social capital is another community-based approach. It tries to influence the positive social networks so that the adolescents feel more connected, more supported, and are provided access to necessary resources such as extracurricular activities, condoms and sexual education through these enhanced support networks.
- **Societal level:** Mass media campaigns can be an effective tool for reaching adolescents who may not otherwise be exposed to interventions. Societal-level changes can also promote increased accessibility to and acceptability of STI prevention and control services for adolescents. Implementing policy initiatives such as adolescent partner notification and partner-delivered treatment may also be critically important.
- **A socioecological approach:** Effective STI prevention and control programs can best be achieved by "synergizing" these 5 levels of interventions (vide supra). STI-prevention resources should be linked into an efficient network. This network, for example, would consist of the community, schools, health providers, local government agencies, and nongovernmental agencies or community-based organizations. The role of this network would be to link resources thereby enhancing preventive services. For example, multiple access points (i.e., recreation centers, after school programs, and physicians' offices) could be used as opportunity sites for providing STI-

prevention information and motivating adolescents to adopt relevant health-promotion skills.

## Designing an Effective Educational/Behavioral Intervention<sup>56–60</sup>

Four main components of effective behavior change projects are

1. Information: Increase awareness and knowledge.
2. Social and self-regulative skills: Provide tools for effective prevention.
3. Guided rehearsal and corrective feedback: Enhance skills and self-efficacy in high-risk situations.
4. Social support: Aid and reinforce personal change efforts.

Various steps involved in designing such an intervention are

### Step 1: Assess the problem

- A. Identify one HIV/STI problem in your community that can be addressed by an educational behavioral intervention and describe it in as much detail as possible. Examples are poor attendance at the local STI clinic, inability of women who are seen at a particular STI clinic to recognize STI symptoms and obtain treatment in a timely manner, lack of access to condoms by sex workers in a particular brothel, higher prevalence of STIs and HIV among long distance truck drivers, etc. Who are the stakeholders? Who in the community is interested in solving this problem and what is their agenda? It could be hospital administrators, the target population, the government, or policy makers.
- B. What information do you need in order to quantify or define the problem, as it currently exists? How will you obtain this information? This will help you to establish a baseline for further evaluation of your intervention. This information can be obtained by key informant interviews (people who know the extent of the problem), from vital statistics records (e.g., deaths), surveillance data (e.g., numbers of people who have HIV/AIDS in a particular population), need assessment survey (sample your target population, could ask about knowledge, beliefs, practices, barriers to practice, very important to be as specific as possible when asking about practices), chart review, number of condoms purchased from the market, published literature, and so on. Are there any barriers to getting a fairly, accurate measure of this problem? What are they? Need to think about these barriers if key stakeholders want evidence of change that you can't deliver. They need to know this at the beginning.

### Step 2: Describe the audience or target population

It is essential to identify important groups that will need to be reached in the community. Different sections of public will have different information needs and will require separate and distinct approaches and messages. Possible target audience may be school children, school teachers, young persons (college and out of college youths), married couples, sex workers and their clients, patients at STI clinics, injecting drug users, homosexual

men, professional groups (e.g., health workers), traditional healers, quacks, religious and community leaders, employers and trade unions, parents, journalists, etc.

Describe the audience who will be targeted by this intervention by using factors given below. These factors will guide you to design your intervention. Please note that these are issues that you need to know about, but this does not replace the need to conduct an actual need assessment of the issues.

- A. Intrapersonal factors: They will include the knowledge, attitudes, beliefs, norms, culture, motivations, self-esteem, self-efficacy, and practices of the population that will support or impede them from making necessary changes. Readiness of this population to make change needs to be considered.
- B. Interpersonal factors: Under this, comes the social networks, social support, families, work groups, peers, neighbors, social norms, and other interpersonal factors that could help support or impede this population from making the desired change.
- C. Resources or lack of resources: They either support or impede this population's ability to make necessary changes. Potential barriers to access these resources also need to be understood.

### Step 3: Assess the organization

Assess the strengths of your organization and what it can contribute to developing the program to help solve the problem. What internal resources and support do you have (administrative support, staff, volunteers, expertise in treating patients for STIs, space, equipment)? What programs already exist that might be models for the program you want to develop? Think about what other organizations you would work with to carry out this program. How this program which you develop can best complement other existing interventions?

### Step 4: Write measurable and specific goals and objectives

- A. **Goal/outcome objective:** Outcome objective is a long-range goal, usually a quantitative measure of behavior or health problem. Setting realistic outcome objectives depends on having current baseline data. If rapid reduction in seoprevalence is not possible, slowing the rate of increase of HIV infection is a logical effective program.  
Set one goal or outcome you want to see. It happens as a result of the programs, you want to develop. This goal should be broad in scope. For example, to reduce further increase of HIV and STIs in long distance truck drivers at a given place at the end of 2 years of intervention.
- B. **Objectives:** These should be measurable objectives that will enable you to reach your goal.
  - i. **Program/process objectives:** "Process objectives" describe key activities essential to achieving the impact objectives. They are often used in pilot tests to determine changes needed before final production. They can be used as markers of progress.  
These "process objectives" describe the process you need to go through to develop and implement your

program. Examples are, putting together a planning committee by the end of 1999, hire all necessary staff by February 2000, sign agreements with all of the participating partners on the project by March 2000, carry out intervention by August 2000, etc.

- ii. **Learning objectives:** They are required to measure intended effect on an individual or group as a result of going through the program and perceived changes in how they think, feel, or behave after the program. Participants will be able to describe the ways in which HIV is transmitted, discuss how they feel about negotiating condom use with their partners, how they are encouraged to purchase condom in a drug store, and use them properly are some of the examples.
- iii. **Impact objectives:** Impact objectives are statements of the program's intended accomplishment in the immediate future. They are often a measure of knowledge, attitude, and behavior from survey and other methods.

These objectives describe the changes that can be observed as a result of the program. Examples are: 6 months after the program is initiated the number of condoms purchased in the specified area will increase by 25%; 6 months after the program is initiated, the number of women coming to STI clinic will increase by 15%; 3 months after the program, hospital policies will change to make it easier for providers to do STI/HIV counseling.

### Step 5: Choose educational models and methods

Which educational model and method or combination of models and methods are best suited to your problem. Examples of models are training course, training of trainers, peer education, mass media. Various methods that can be adopted are lecture, role-playing, demonstration, discussion, interactive exercises, video, brochure(s), or posters.

### Step 6: Implementation

Various components are

- A. Plan for securing speakers/trainers/other necessary staff/ putting together a planning committee. Be sure to include your target population as part of this committee.
- B. Plan for securing or developing educational materials.
- C. Plan for securing other training materials/equipment/ location.
- D. Plan for marketing your program.
- E. Develop a budget for your program.
- F. Develop a time line for your program (be realistic).

### Step 7: Assess effectiveness

It is important to consider the stakeholders and include them in the process of deciding what types of information they would like to have demonstrated to show that the program has been successful. Look at the different types of objectives that you have written; which of these objectives would you need to evaluate to satisfy the stakeholders? Some stakeholders may want you to

**Table 10.1:** Health Campaign Elements

1. Community strategies	—organizing, public relations, coalition building
2. Social control measures	—regulation, legislation, policy, taxes
3. Mass media	—print, electronic, broadcast, small media
4. Health services	—availability, access, funding
5. Economic factors	—removing barriers
6. Environmental factors	—removing barriers
7. Interpersonal approaches	—outreach, counseling, advocacy
8. Evaluation	—cost benefit, process, impact, outcome

demonstrate actual changes in STD rates in your community which are difficult to show in short term and, in addition, there may be other projects going on in your community that are working on the same problem that could also impact these rates.

Assess your program/process objectives (e.g., to show proof that staff was hired by the date you indicated), learning objectives (e.g., develop a pre-post test to determine if participants learned what you intended them to learn or you could observe what they have learnt) and impact objectives (e.g., count how many more patients have come into your STD clinic, do chart reviews, get an internal audit of condom purchases and how they have changed, show that you have a new policy in place).

Various elements of any health campaign are summarized in Table 10.1.

### STUDY DESIGNS IN ASSESSING EFFECTIVENESS OF BEHAVIORAL INTERVENTIONS

Considerable debate still centers on whether the randomized controlled trial should be considered the gold standard for evaluating the impact of behavioral interventions.<sup>61–64</sup> Despite considerable achievements, behavioral science is often viewed with skepticism by practitioners of biomedical science.<sup>6</sup> Studies that rely on “self reports” of participants and research designs that lack random assignment to isolated conditions are viewed as weaker than true experiments that incorporate biological markers as outcomes. However, traditional experimental methods are often hopelessly inapplicable to studies of risk behavior as practiced and are of limited feasibility in the evaluation of fledgling community public health programs. By contrast, the evidence based approach to the evaluation of healthcare interventions views the randomized trial as optimal research design for this purpose because of its ability to minimise bias and avoid false conclusions about what works and what does not. To accept the randomized trial as the gold standard, however, is not to deny its limitations and challenges, particularly in behavioral or psychosocial field.<sup>5,64</sup>

A frequent objection to randomized trials of behavioral interventions relates to the ethics of “with holding” the intervention from a control or comparison group.<sup>5,64</sup> Faced with the enormity of HIV epidemic and the urgent need to find effective behavioral interventions to combat its spread, there has been a tendency to think that action (implementing behavioral interventions) must be preferable to inaction.<sup>5</sup>

It has also been argued that randomized trials are not appropriate for evaluating behavioral interventions because they ignore the complexity of behavioral and psychosocial interventions.<sup>64</sup> Behavioral or psychosocial interventions are more likely to resemble a “black box”, in which the “active ingredient” has not been identified. Perhaps the greatest challenge, in the behavioral field, is to design and conduct trials in such a way that delivery of the intervention can be standardized as much as possible.<sup>5</sup>

### Behavioral Interventions and Outcome Measures in HIV/STI Prevention

Choice of outcomes by which to assess the success of a behavioral intervention is the key issue.<sup>45</sup> The ultimate goal of such intervention is to reduce the rate of new HIV/STIs in defined groups or populations, and many innovative interventions have been set up throughout the world with this goal in mind, but no randomized trial has yet reported the impact of a behavioral intervention on HIV incidence.<sup>61,65</sup>

Although most would agree that HIV seroincidence would be the strongest evidence used to assess the public health impact of HIV prevention studies, this assessment is often not possible if there is a low incidence of HIV in the population being studied.<sup>66</sup> Thus, many recommended that STIs should be used as surrogate markers for HIV, despite the fact that the true empirical relationship between a given STI and HIV has not been established. Under the circumstances, however, acute (non HIV) STIs are suitable end points for behavioral interventions trials because they are important causes of morbidity in themselves, they occur more commonly than HIV infection, and have been clearly shown to increase the risk of HIV transmission.<sup>67,68</sup>

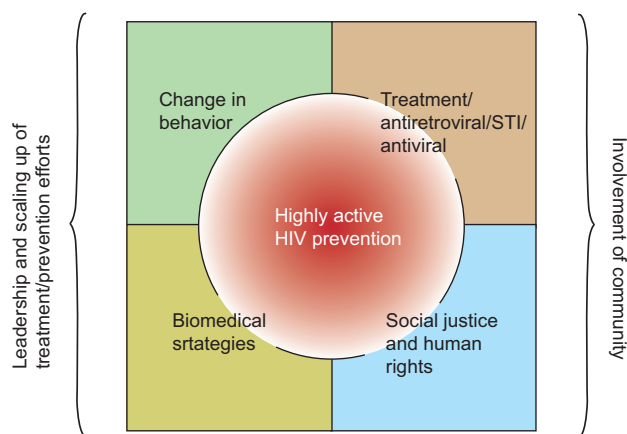

By analogy, the success of a behavioral intervention trial may be influenced by rapidly changing social and community norms in relation to sexual behavior. Changing sexual behavior through specific interventions is no easy task, and experience in other fields suggests that we should not expect big effects, as experimental interventions encompass only a segment of what social movement brings to bear.<sup>5,69</sup>

It will be useful to assess the effects of a behavioral intervention on both behavioral and biological outcomes.<sup>43</sup> Even in the absence of biological measures, behavioral self reports can provide useful information about the efficacy and effectiveness of behavior change interventions.

### LIMITATIONS OF BEHAVIORAL INTERVENTIONS AND NEWER APPROACHES

Studies have shown that behavioral interventions alone did not produce any satisfactory decrease in the pandemic spread of HIV. An integrative package that includes biomedical, behavioral, and structural interventions offers the best method of preventing HIV spread. The combination of multimodal prevention strategies are needed to maintain adherence, to avoid sexual disinhibition (risk compensation), and are essential for

**Fig. 10.2:** Highly active HIV prevention.<sup>2</sup> (This term was coined by Prof K Holmes, University of Washington School of Medicine, Seattle, WA, USA).

addressing mechanisms that will scale up the optimized effects. The biomedical interventions that are effective in prevention include use of male condoms; male circumcision; and prophylactic use of antiretroviral drugs or contraception to prevent unwanted pregnancies and to reduce mother-to-child transmission. Oral and vaginal antiretroviral drugs both for pre-exposure prophylaxis and to reduce infectiousness among HIV-positive individuals are being assessed. Female-initiated methods, including physical barriers and topical antimicrobials (vaginal microbicide) products should be promoted.<sup>49</sup>

For the past two and a half decades, HIV prevention has been dominated by individual-level behavioral interventions that seek to influence knowledge, attitudes, and behaviors, such as promotion of condom use, or sexual-health education, and education of injecting drug users about the dangers of sharing equipment. Individual-level behavioral interventions have been successful to a limited extent, and it has shown that structural interventions substantially improve the outcomes of such a strategy. Structural interventions refers to addressing social, economic, political, and environmental factors (like poverty and wealth, gender, age, policy, and power that eventually shape or constrain individual behavior) and seek to change the root causes that affect individual risk and vulnerability to HIV. These are long-term initiatives that belong within the purview of broader economic and social development.<sup>70</sup>

Thus, the realm of “highly active HIV prevention” can be conceptualized as shown in Fig. 10.2.

## Conclusion

Research on HIV prevention during the past decade has identified numerous models, at levels ranging from individual interventions to public policies capable of affecting an entire population.<sup>71</sup> None of these approaches should be considered sufficient in itself because, put simply, it is well-known that behavior is difficult to modify. This truism is especially applicable when the behavior is determined by many factors and serves many needs, as is the case

with sexual behavior. Therefore, each of these approaches should be seen as one part of a comprehensive HIV/STI prevention program. Such efforts need to target individuals, small groups, communities, schools, and social policies. Adoption of theoretically guided and empirically validated approaches promises most success. There remains an urgent need to develop and tailor HIV prevention approaches that can promote the maintenance of behavior change, to reach community segments that remain vulnerable, and to address the changing context of the epidemic.<sup>72</sup> Finally, the fundamentals of HIV prevention need to be agreed upon, funded, implemented, measured, and achieved in a comprehensive and sustained manner.<sup>2</sup>

## Condoms and Other Barrier Methods of STI and HIV Prevention

Richard A. Crosby • Seth Noar  
• Sara Head • Elizabeth Webb

### Introduction

This chapter will briefly review what is known about the effectiveness of condoms against sexually transmitted infections (STIs), including HIV. The chapter will then provide an in-depth examination of the behavioral and political issues that ultimately create challenges to condom use promotion thereby mitigating the ability to easily prevent infections. Novel interventions designed to promote the consistent and correct use of condoms will be reviewed. Subsequently, the chapter will review several barrier method alternatives to condoms, with an emphasis on the emergence of vaginal microbicides.

### Condom Effectiveness

In the year 2001, the United States Department of Health and Human Services issued a report on a workshop designed to assess the effectiveness of latex condoms for the prevention of STIs.<sup>1</sup> The report cited evidence that condoms are effective in preventing HIV transmission and female-to-male transmission of gonorrhea, but stated that empirical evidence was insufficient to evaluate the degree of risk reduction provided by condoms in regards to chlamydia, trichomoniasis, syphilis, chancroid, genital herpes, and human papillomavirus (HPV). An unfortunate outcome of this report was that opponents of safer sex programs interpreted the lack of evidence to mean that condoms do not work rather than simply concluding that the evidence had not yet been collected. While considerable controversy followed this report, the critical implication did indeed involve the need for further research on condom effectiveness. As the report noted, “to definitively answer the remaining questions about condom effectiveness for preventing STI infections will require well-designed and ethically sound clinical studies.”

In the years that followed the report, several studies were published that either provided further evidence of condom effectiveness, critiqued the methodology of the panel generating the report, or provided methodological guidance for further studies of condom effectiveness.<sup>2–10</sup> Further, the National Institutes of Health (US) funded a large multisite, prospective,

evaluation of condom effectiveness against biologically assessed nonviral STIs.<sup>11</sup> While more studies are still needed, two realities are apparent: (i) methodological issues inherent in the study of condom effectiveness have consistently created a bias toward the null<sup>4–6,9,10</sup> (meaning that results unfairly favor the hypothesis that condoms are not effective), and (ii) it has become apparent that the consistent and correct use of latex condoms offers considerable protection against most STIs, including even HPV<sup>8</sup> and genital herpes.<sup>7</sup>

To summarize the evidence briefly, the panel of experts commissioned for the 2001 report evaluated 138 published studies that provided evidence regarding the effectiveness of condoms against HIV and seven other STIs.<sup>1</sup> Only studies reporting evidence pertaining to the transmission of STIs through penile-vaginal sex were reviewed. The panel agreed that the quality of male (latex) condoms was very high and that *in vitro* evidence supporting a potential protective effect was strong. Indeed, *in vitro* assays have consistently shown that the porosity of condoms is protective against even the smallest sexually transmitted pathogens (e.g., viral STIs, including HIV).<sup>12</sup> Although the panel concluded that condoms do prevent female-to-male transmission of gonorrhea, they noted that evidence was (at the time) insufficient to judge the adequacy or inadequacy of condoms for the prevention of male-to-female transmission of gonorrhea and for the prevention of six other STIs. Evidence regarding condom effectiveness against HIV acquisition and transmission was very strong—primarily because of rigorous studies among serodiscordant couples<sup>13,14</sup>—thus, the panel concluded that consistent and correct use of latex condoms is highly protective against HIV infection. Beyond the US report, studies have provided evidence of condom effectiveness against chlamydia<sup>15–17</sup> and male-to-female transmission of gonorrhea.<sup>17–20</sup> At least one study provided evidence suggesting that condoms are protective against trichomoniasis.<sup>17</sup>

Although much more research remains to be conducted regarding condom effectiveness (especially relative to penile-anal sex and penile-oral sex), it is quite fair to say that the current need is to precisely quantify the degree of protection

offered by condoms rather than debating the specious question of whether or not condoms work at all. In addition, and more importantly, sufficient evidence supporting condom effectiveness against various STIs has accumulated to warrant the expansion of condom use research into the intricacies of behavioral research.

## Behavioral Research

In this section of the chapter, we address key behavioral issues pertaining to the use of condoms. For convenience, the issues are divided into (i) use of condoms, and (ii) correct use.

### PROMOTING THE USE OF CONDOMS

Much data exist on the prevalence of condom use among adolescents and young adults. Recent data indicate that condom use has been increasing over time among US adolescents. For example, national surveys indicate that condom use at last intercourse increased from 46% in 1991 to 62% in 2007.<sup>21,22</sup> While hormonal birth control use has remained unchanged over that same period of time, the prevalence of condom use increased during 1991–2003 and then leveled off during 2003–2007. These increases have been detected in all major racial/ethnic groups, including African-American, Hispanic, and white adolescents.<sup>21,22</sup>

Consistent condom use also appears to be increasing with the passage of time. Where surveys of US adolescents have tended to find rates of consistent condom use to be below 50%,<sup>23</sup> recent data suggest that rates of consistent condom may now be in the 50%–80% range (15–19 year olds).<sup>22</sup> These and other data also indicate that condom use is higher among males than females and higher among African American adolescents as compared with white and Hispanic adolescents.<sup>21,22,24</sup> National studies have also found condoms to be used more among higher risk populations, such as those with multiple sexual partners.<sup>25,26</sup>

Studies of young adults suggest lower rates of condom use than that of adolescents. It should be noted, however, that data on young adults are not as recent due to the fact that surveillance surveys in the United States tend to be conducted with adolescents or adults. Nationally representative studies of young adults have found rates of consistent condom use among sexually active 18–29 year olds to be as low as 7%<sup>27</sup> or higher at 16% or 24%.<sup>28</sup> A large survey of undergraduate college students found 88% to be sexually active but only 18% to use condoms consistently.<sup>29</sup>

A rather robust finding in studies of condom use is that individuals are more likely to use condoms with secondary or casual sex partners than with main or steady partners. For example, while Anderson and colleagues found 62% of individuals to use condoms at last intercourse with secondary partners, only 19% were found to use condoms with main or steady sexual partners.<sup>24</sup> This finding has been replicated across numerous populations, including heterosexual and homosexual adolescents and young adults, injection drug users, and commercial sex workers (CSWs).<sup>5,29,30</sup> This phenomenon appears to be the result of individuals having vastly differing perceptions of risk of the

two types of partners.<sup>31,32</sup> In fact, a recent study of 1489 young adults<sup>32</sup> illustrates this point. In this study, young adults were asked to rate the likelihood that an individual would get an STI or get pregnant if they had unprotected sex with a main/steady versus casual partner. No differences were found on pregnancy, as young adults reported a high likelihood that unprotected sex would lead to pregnancy with both types of partners. In contrast to this, whereas 80% of the sample reported that it was likely that unprotected sex with a casual partner would lead to an STI, only 33% of the sample reported this for a main/steady partner.

Research has suggested that a variety of psychological processes within intimate and sexual relationships play into the perception that main/steady partners are automatically safe partners.<sup>5,29,30</sup> In particular, factors that can impede condom use in main partnerships include trust and intimacy. While trust is generally a positive dimension within intimate relationships, in the sexual context it can undermine condom use.<sup>33–35</sup> For example, the *contraceptive switch* (discussed more below) that some couples make when they go from condoms to hormonal birth control is seen as an intimate and trust-building step in both adolescent and young adult relationships.<sup>33,36</sup> Some studies have further found an association between trust and commitment-related beliefs and condom use. For instance, the belief that asking a partner to use condoms means you are implying they are unfaithful,<sup>35,37</sup> and the belief that losing a partner may mean losing additional friends and family<sup>38</sup> have both been found to be related to lower rates of condom use. Perceptions of greater relationship quality and intimacy have been associated with lower rates of condom use in several studies of adolescents.<sup>39–41</sup>

Moreover, in some cases, adolescents engage in unsafe sexual practices with their main partner to demonstrate trust.<sup>34</sup> In addition, in the context of a close relationship, studies have found condoms themselves to be perceived as representing *mistrust*, and their very presence can arouse suspicions of cheating.<sup>28,35,37,42</sup>

Another important issue in this area has to do with how condom use changes over time in relationships. Ku and colleagues has proposed the *sawtooth hypothesis*, which posits that within a close relationship, condom use will vary over time, with the direction of condom use decreasing and creating a *sawtooth* pattern.<sup>43</sup> Using data from the National Survey of Adolescent Males (NSAM), they demonstrated that condom use tends to be highest at the beginning of a relationship and decrease over the course of a relationship. Specifically, they reported that 53% of young men used condoms at initial intercourse with their close partner, whereas only 44% used condoms with that same partner at their most recent intercourse occasion. In addition, use of other contraceptive methods followed the reverse path. Namely, only 29% of young men's partners used birth control (other than condoms) at initial intercourse with their close partner, whereas 48% used birth control with that same partner at their most recent intercourse occasion. Other researchers have found support for the notion that as relationships progress, condom use diminishes.<sup>38,41,44</sup> These and other data support the notion of the *contraceptive switch*, or the idea that partners

start off using condoms, and then as the relationship progresses move to a hormonal contraceptive method such as birth control pills.<sup>33,36,43,45</sup> The implication here is that once a couple has been together for a period of time, they no longer view one another as a potential STI risk. Switching from condoms to birth control pills, while perhaps viewed as more convenient for the couple, leaves the couple unprotected from STIs that one or one's partner may have.

Interestingly, studies suggest that the period of time that elapses before condom use begins to diminish is rather short. Fortenberry and colleagues reported, in a longitudinal study of adolescents and young adults, that condom use stopped in most relationships at approximately 3 weeks after initiation of sex.<sup>44</sup> This suggests that the perceptions of a new or casual partner change to perceptions of a main/steady partner within a relatively short period of time.

A large literature also demonstrates the importance of both belief systems and skills to the enactment of condom use among adolescents and young adults. Youth are more likely to use condoms if they have positive attitudes toward them and they perceive that others in their peer group also use condoms.<sup>46,47</sup> One particularly salient belief, especially among men, is the belief that condoms reduce sexual pleasure. Numerous studies demonstrate that those who hold this belief are less likely to use condoms than those that do not hold this belief.<sup>47,48</sup> It is for this reason that intervention programs to increase condom use often emphasize the eroticization of condom use,<sup>49</sup> in attempts to make condoms more erotic and acceptable in sexual encounters.

Moreover, data indicate that one of the strongest psychosocial predictors of condom use is condom self-efficacy,<sup>47,50</sup> or the perceived ability to use condoms in a variety of situations. Those who have high self-efficacy (or confidence) are able to use condoms even in challenging situations, such as when they are under the influence of alcohol or drugs, when they perceive the risk of a partner to be low, or when they get caught in the "heat of the moment."<sup>51</sup> Unfortunately, low self-efficacy may lead to unprotected sex even when an individual had intended to use condoms.<sup>52</sup> Skills training to address strategies for enhancing self-efficacy are often taught in HIV prevention interventions in efforts to boost participants' condom self-efficacy.<sup>50</sup>

Finally, studies have demonstrated that communication and negotiation skills are critical to the enactment of condom use.<sup>53</sup> In fact, self-reported partner communication about condom use is one of the strongest predictors of actual condom use.<sup>47,54</sup> In many ways this is not surprising, since it is often necessary for one individual (often the female) to communicate a desire to use condoms with a sexual partner (often the male). In the absence of good communication and negotiation skills, condom use may not take place.<sup>53</sup> Moreover, this is another focus of preventive interventions, in that numerous HIV prevention interventions teach individuals how to bring up the topic of safer sex as well as how to negotiate condom use with a resistant sexual partner.<sup>55</sup>

Given the strong associations of many of these psychosocial variables to condom use, a number of behavioral theories (that

contain these variables) are often used as bases for HIV prevention behavioral interventions.<sup>56</sup> Although each theory differs in various ways, most contain a set of similar psychosocial variables.<sup>57</sup> One popular theory, which summarizes such variables in a parsimonious fashion, is the information-motivation-behavioral skills (IMB) model.<sup>58</sup> This theory suggests that whether an individual will engage in condom use is a function of three factors: (i) a person's knowledge about HIV prevention practices and condom use; (ii) a person's motivation to engage in condom use, including their perceptions of risk of STI/HIV, their attitudes toward condoms, and their perceptions of social norms about condom use; and (iii) a person's behavioral skills for enacting condom use, such as perceived self-efficacy and condom communication and negotiation skills. The IMB model suggests that a person must have the knowledge, motivation, and skills to effectively enact condom use in sexual situations, and such a model helps us understand why individuals with only the knowledge (but not the motivation and/or skills) fail to engage in safer sex. Given this proposition, scores of behavioral interventions have been based upon the IMB model and/or similar behavioral theories, in efforts to affect these psychosocial variables and ultimately impact condom use.<sup>57,58</sup> Reviews and meta-analyses of such intervention programs suggest that such behavioral interventions are generally efficacious in increasing condom use and affecting other sexual risk behaviors.<sup>59,60</sup>

Of course, one of the most important behavioral issues relevant to condom use involves patients of STI clinics. A critical question for clinicians working in clinics that diagnose and treat STIs is whether patients are more likely to use condoms after being diagnosed with an infection. A recent study evaluated this question with respect to a new diagnosis of HSV-2 infection.<sup>61</sup> In a 3-month prospective study of men and women attending an STD clinic in the US, 43.4% (111 people) of those completing follow-up questionnaires, tested positive for HSV-2 at enrollment. Significant differences (assessed at follow-up) between persons testing positive and persons testing negative were not found for frequency of condom use. When analyzing change (baseline to follow-up) among only those testing positive, significant differences were not found with the exception of reporting greater frequency of condom use with steady ( $p = 0.037$ ) and non-steady partners at follow-up ( $p = 0.017$ ).

A final behavioral issue, and perhaps the most substantial, involves the observation that is all too obvious—this method of disease prevention is simply not acceptable to women (or couples) desiring conception. In many settings, sociocultural expectations for married couples, such as the assumption of monogamy in marriage or societal pressure to conceive, do not encourage condom use in married relationships. Indeed, worldwide, condom use among married couples is low.<sup>62</sup> This is unfortunate considering that in many regions heterosexual sex with one's husband has become a major HIV risk factor for women,<sup>63–68</sup> implying that husbands acquire STIs or HIV in extramarital relationships and then infect their wives. Of course, either spouse may engage in extramarital relationships

and present potential STI/HIV risk to their partner, but in many countries, married men are more likely to engage in premarital or extramarital sex because it is more acceptable for or expected of them.<sup>69–73</sup> Thus, the role of condoms in the prevention of STIs and HIV in married relationships has become an important focus and one heavily nuanced by a culture's gender norms and views on sexuality.

In South Asia, for example, condom use is often identified with contraception.<sup>74</sup> Married women in this region are under considerable pressure to demonstrate fertility and to bear sons.<sup>75,76</sup> In India and Bangladesh, where the birth of sons secures a woman's social and economic position,<sup>77,78</sup> the use of condoms in a married relationship interferes with this goal, and therefore, with the woman's realization of her culturally sanctioned gender role.<sup>74</sup> Research in China indicates that married couples at risk for STIs and HIV (couples in which the husband is a migrant worker) are less likely to use condoms when the wife is using an alternative contraceptive method.<sup>79,80</sup> In fact, in one study, 80.1% of women responded that their use of another form of contraception was reason for not using condoms.<sup>79</sup> In a qualitative study among married women in Uganda, women report using the contraceptive quality of condoms as a persuasive strategy to introduce condom use to their husbands. In these strategies, women would emphasize that their bodies could not handle other contraceptive methods, or they would cite economic reasons for using condoms as a family planning method. Further, women explained that identifying condom use in their marriage as specifically a contraceptive measure helped to deflect feelings of distrust the introduction of condoms would have otherwise generated.<sup>81</sup>

Indeed, research in a variety of settings finds condom use introduces distrust, suggests marital infidelity, and is identified with promiscuity or sex work, leading some scholars to say that the significance of condoms to feelings of trust and intimacy in a relationship is the central influence on decisions about whether and when a couple uses a condom.<sup>82</sup> Evidence of the condom's interference with intimacy and feelings of fidelity can be found in qualitative research in Malawi. According to data from more than 300 participant diaries, condom use represents risky, less serious, and less intimate relationships. Therefore, even when participants believed condom use to be appropriate, wise, or even a matter of life and death, the capability of condoms to define relationships ultimately determined whether or not a condom was used.<sup>83</sup>

Similarly, in India, condoms are widely perceived as necessary only to prevent pregnancy and infection during sex with CSWs.<sup>72,84</sup> Accordingly, a spouse's suggestion of condom use could make a strong statement against the wife's virtue, raise suspicions of the husband's fidelity, or suggest either spouse is infected with an STI or HIV. This perception may also discourage the purchase of condoms in that people buying condoms may be seen as seeking sex with sex workers.<sup>74</sup>

Most HIV prevention and treatment services currently deal with patients as individuals rather than as members of a married partnership, and interventions promoting condom use in marriage

are few. Research in sub-Saharan Africa, however, indicates that voluntary counseling and testing programs followed by behavioral-change interventions aimed at couples have been shown to reduce HIV transmission among serodiscordant married and cohabiting couples.<sup>85–87</sup>

Also of great importance is the observation that once pregnancy (planned or unplanned) occurs couples are prone to abandon any condom use that had been practiced before conception. In one study, for example, pregnant adolescents compared to their nonpregnant counterparts, reported less overall condom use, more infrequent condom use, and more unprotected vaginal sex.<sup>88</sup> In that same study, pregnant and nonpregnant adolescents were equally likely to test positive for STDs and equally likely to self-report having STDs during a 12-month follow-up period. These findings (and those from other studies)<sup>89–91</sup> suggest that pregnant adolescents may be less likely to use condoms than their nonpregnant peers and that STD incidence among pregnant adolescents may be high even though they are potentially receiving prenatal care. Clearly then, condom use promotion may be critically important as part of adolescents' prenatal care. This is particularly true with respect to those having sex partners known to be infected with genital herpes. Indeed, testing negative for HSV-2 during the first prenatal visit represents a clinical opportunity for counseling and education designed to decrease adolescents' risk of primary HSV-2 infection during the remainder of the gestation period. Evidence suggests that condom use may protect women from HSV-2 acquisition.<sup>92</sup> Given that a substantial portion of neonatal HSV is caused by HSV-1, adolescents could also be counseled to avoid cunnilingus during pregnancy.

An important point about condom use that should also be kept in mind is that heterosexual couples often have a difficult time of achieving condom use when the female partner is using hormonal contraceptives. This is most likely a result of a mismatch between the perceptions of pregnancy likelihood compared to the likelihood of disease transmission. Whereas conceiving is viewed as normal and even a sign of vitality; disease is viewed as an unlikely event given the apparent good health of each partner. In essence, pregnancy prevention may be the primary motivating force behind the use of condoms and once a better method comes along (e.g., hormonal contraceptives) couples may be quick to discard the practice of condom use. This all too common dynamic has spawned research investigating factors that may best be altered to promote the dual use of condoms and hormonal contraceptives.<sup>93–96</sup>

## PROMOTING THE CORRECT USE OF CONDOMS

A nagging question that frequently came up in studies that involved the use of condoms and also assessed incident STDs is, "How is it possible for consistent users to be diagnosed with STDs such as gonorrhea, chlamydia, and trichomoniasis if indeed condoms confer protection." A good example was published by Zenilman and colleagues in 1995.<sup>97</sup> They observed a lack of association between condom use and incident STDs that may

indeed been a consequence of unmeasured confounding. More specifically, the study did not assess whether condoms broke, slipped off, were applied after sex had begun, or were removed before sex was concluded. A subsequent paper published by Crosby and colleagues reported a similarly puzzling finding from a study of adolescent females. Among those reporting 100% condom use, 17.8% tested positive for at least one of three STDs (gonorrhea, chlamydia, or trichomoniasis).<sup>98</sup> A subsequent paper (based on a different sample of adolescent females) demonstrated that by accounting for “fatal errors” in condom use a nonsignificant association between condom use and STDs achieved significance.<sup>10</sup> The unadjusted measure of unprotected vaginal sex was not significantly associated with biologically-confirmed prevalence of STDs (Prevalence Ratio [PR] = 1.51; 95% CI = 0.71–3.21;  $p = 0.28$ ). Alternatively, the adjusted measure achieved significance (PR = 3.59; 95% CI = 1.13–11.38;  $p = 0.014$ ). More than one-quarter (25.6%) of teens using condoms inconsistently and/or incorrectly tested positive for an STD compared to 7.1% among those reporting the consistent and correct use of condoms.

Fifteen years after the study published by Zenilman and colleagues,<sup>97</sup> it is now widely apparent that people make multiple errors when using condoms and that they experience an array of problems; many of which may lead to condom failure and may discourage continued use of condoms. For example, a study of condom-using men found that 43% reported recently putting a condom on after starting sex and 15% recently reported taking a condom off before sex was over.<sup>99</sup> The study also found that 30% placed the condom upside-down on the penis and flipped the condom over before starting sex (thereby potentially transferring infected seminal fluid to the exterior of the condom). In addition, the study identified and assessed four likely problems or outcomes of these errors, including slippage and breakage (reported by 35%). A subsequent study reported remarkably similar findings for condom-using women<sup>100</sup> (including a specific analysis of those who applied condoms to their male partners).<sup>101</sup> Indeed, frequent condom errors and problems for both men and women have been reported by several research teams.<sup>102–107</sup> For example, it is possible that “incomplete use” of condoms is quite common.<sup>100,103–105</sup> This occurs when condoms are applied after penetration or removed before withdrawal.

Avoiding user errors in condom use is critically important to the control and prevention of STDs. For example, incomplete use may be based on the event of ejaculation. That is, the condom may be used only immediately before and during ejaculation. It is also conceivable that incomplete use is associated with perceived erection problems.<sup>108–110</sup> Two problems (breakage and slippage of condoms) are, of course, critical concerns. Thus, an important sub-question is, “What are the errors that lead to condom breakage?” and “What are the errors that lead to condom slippage?”

A study of men attending an STD clinic provided some initial evidence suggesting reasons why condoms may break during penile-vaginal sex.<sup>111</sup> Each of 278 men provided reports about the last 3 times they used condoms thereby creating 834 observations.

Men reported breakage during 125 of these occasions, making the breakage rate 15.0%. Eighty-seven men (31.3%) reported breakage during at least one of the 3 occasions of penile-vaginal sex. Men who reported a previous history of STI were about twice as likely as those reporting they had never had an STI to report breakage. In multivariate analyses, men who reported problems with condom slippage were about 2.5 times more likely to also report breakage. In addition, men with relatively lower self-efficacy to use condoms correctly were about twice as likely to report breakage. Three primary causes of breakage were identified. Men who reported that condoms had contacted a sharp object were about 2.6 times more likely to report breakage than men saying condoms did not contact sharp objects. Also, men reporting problems with the “fit or feel” of condoms were about 2.3 times more likely to report breakage than men not having this difficulty. Finally, men reporting that they had not squeezed air from the receptacle tip were about twice as likely to report breakage. Although more investigation regarding why problems with “fit and feel” may cause breakage is needed, some evidence suggests that tight fitting condoms may be the link between “fit and feel” problems and breakage.<sup>112–116</sup> In another study of men, those who had used an oil-based lubricant were more than 3 times as likely to report breakage and those who completely unrolled the condom before putting it on were also about 3 times more likely to report breakage.<sup>117</sup> Of course, it is quite likely that other potential causes of condom breakage will be identified; however, the overarching conclusion is unlikely to change: condom breakage may be averted through the improved selection (for fit) and application of condoms.

In a study that combined the events of condom breakage and slippage,<sup>118</sup> it was observed that men who report that their partners were not “highly motivated” may be more likely to report condom breakage/slippage. Higher number of partners and more frequent condom use were associated with condom breakage/slippage. Finally, men who had never been instructed about correct condom use were about twice as likely to report breakage/slippage as compared to those indicating they had received this form of instruction. Unfortunately, only a handful of studies have specifically investigated the possible causes of condom slippage. One, for example, used an event-level analysis (meaning that the measures used all pertained to the same act of sex) and found that slippage was about 5 times more likely among men reporting they had used phosphodiesterase type 5 inhibitors (erection enhancing drugs) when having sex.<sup>119</sup> The reasons why prolonged erection from these drugs may lead to slippage are not known at this time. However, it is increasingly apparent that erection issues and condom slippage are related. For example, a study of college students found that those who reported at least one instance of erection loss *during condom application* (just over 1/7 of the sample) were more than twice as likely to report that the condom had slipped off. Also, those who reported at least one instance of erection loss *during sex* (just over 1/6 of the sample) were more than 4 times as likely to report slippage.

The same study also found that slippage was more than twice as likely when lubrication of the condoms was poor.<sup>119</sup>

Of course, one of the best ways to truly appreciate the issues surrounding the correct application, correct use, and enjoyment of condoms is to consider findings from qualitative studies. For example, in a recent qualitative study of African American men (conducted by the first author) newly diagnosed with a sexually transmitted disease (STD), one theme that emerged was that men did not exercise unilateral control over condom use.<sup>119</sup> This is an important observation as it often assumed that men are completely able to control whether or not condoms are used. Evidence does suggest that the quality of condom use is also greater when both the male and female partner in a heterosexual relationship make the decision to use condoms on a mutual basis.<sup>120</sup> Men in the qualitative study also described condoms as physically detracting from sex and simultaneously enhancing the experience through the relief of anxiety pertaining to disease and pregnancy. One man, for instance, stated, “It (condom use) was better for my mind but to my body it was worse.” Another man stated, “I’m starting to enjoy using a condom even though there’s nothing like natural sex...but with all of these diseases...” Despite perceptions about the added mental pleasure from condom use, men were nonetheless clear about the loss of physical sensation. For most, however, the trade-off between “peace of mind” and loss of skin-to-skin contact seemed worthwhile. One man provided an extremely interesting perspective: “I think personally that when you use a condom you can go longer.” Findings from another qualitative study<sup>112</sup> also make some of the condom use errors and problems quite salient. For example, regarding condom lubricants one young man stated, “It (baby oil) suites me better—it creates more slip and slide.” Another stated, “If it (the condom) dries out I usually put lotion on or whatever I can find.” Regarding condom availability, one quote seemed to describe the sentiments of many men: “Late at night you don’t have time to look around—you use what you can get.” Although a vast number of other condom use issues could be examined qualitatively in this chapter, the important point to bear in mind is a simple one: condom use (unlike sex) is a learned set of actions that are seldom taught to people, hence the knowledge and skill levels of vast numbers of men and women are inadequate to achieve condom use that is not only correct (mechanically) but also enjoyable. It is also vital to keep in mind that condom use is only a small part of a much larger behavior—sexual intercourse. The sexual rituals and “rules” that couples follow when they have sex may have a much larger influence on their condom use behavior than is realized. With each new partner and with each established partner the process of negotiating for condom use and actually using condoms may shift and change as function of the relational and sexual dynamics. Indeed, this observation may explain a rather robust finding that incorrect condom use is more likely to be reported by men having multiple sex partners.<sup>122</sup>

## CRITICAL EMPIRICAL GAPS REGARDING CONDOM USE

Unfortunately, the empirical literature base relative to condom use has developed with a strong bias toward penile-vaginal sex thereby neglecting research studies evaluating the behavioral issues relative to condom use during oral and anal sex. Very little, for example, is known about the use of condoms for oral-genital sex among couples (gay or straight). One fairly robust observation has been that condom use for oral sex is extremely rare.<sup>121,123,124</sup> In a study of college students, 80% of those engaging in oral sex had never used a condom even though they were knowledgeable of the STD risk associated with oral sex.<sup>125</sup> In a study of young people in the United Kingdom, fewer than 2% reported consistent condom use for oral sex.<sup>126</sup> Various reasons for not using condoms during oral sex have been identified. These include the belief that oral sex feels better without a condom,<sup>50</sup> the dislike of the taste of condoms, and problems negotiating oral condom use with a partner.<sup>126,127</sup>

One recent study did find enough variance in condom use for oral sex to allow for comparisons between those never-using condoms for oral sex (in the past 3 months) and those using condoms at least once for oral sex in that same recall period.<sup>128</sup> The majority of the 353 study participants (82.1%) never used condoms for oral sex while the remaining 17.9% used condoms for oral sex at least once in the 3-month recall period. Those who engaged in relatively higher penile-vaginal sexual frequency, defined as 12 or more sexual acts and measured within the last 3 months, were almost twice as likely to report never use of condoms for oral sex. All of the participants who never used condoms for penile-vaginal sex reported they never used condoms for oral sex. Of interest, the study compared people recruited from a college campus and an STD clinic: those recruited from the college campus were 6 times more likely to report never using condoms for oral sex in the past 3 months. In a study of more than 700 African American adolescent females, nearly one of every 2 adolescents (45.5%) reported they had performed oral sex on a male partner in the past 60 days. Of these, 88.9% ( $n = 288$ ) indicated having one or more episodes of unprotected oral sex (UOS) in that time period thereby meaning that just under 12% did indeed use condoms for oral sex.<sup>129</sup> One likely problem that women may have with condom use during fellatio is the taste and smell of condoms. In a study of nearly 500 heterosexually active men and women from multiple countries, it was observed that 35.4% reported that the smell of condom was a sexual “turn off” and 16.7% reported that the taste was a turn off.<sup>130</sup> Of note, a roughly comparable portion of men indicated that smell was a turn off but less than 8% said this about taste (as might be expected among heterosexual men).

Of course, the bias toward investigating condom use for penile-vaginal sex has also resulted in a dearth of data regarding condom use for anal sex. Anal sex is often regarded as a homosexual behavior occurring between men who have sex with men (MSM) since the majority of research has focused on anal sex as a risk factor for STIs and HIV among this population.<sup>131–135</sup> However, research also indicates anal sex is prevalent among heterosexual

populations,<sup>134–136</sup> including adolescents.<sup>137,138</sup> Anal sex presents a heightened risk for HIV transmission over penile-vaginal or oral sex<sup>139</sup>; thus the promotion of condom use for anal sex among all populations practicing it is crucial to HIV prevention.

Condom use with anal sex is frequently reported to be low and inconsistent across all groups and in a variety of countries.<sup>140–144</sup> A number of cognitive and behavioral issues may account for this. For example, studies report the perception among adolescents that anal sex is not considered sex.<sup>145</sup> There is also evidence from Latin America indicating that women may engage in anal sex as an alternative to penile-vaginal sex in order to preserve their virginity.<sup>146</sup> Both these beliefs may impact how youth translate HIV preventive condom use messages and their use of condoms with anal sex. Additionally, the fact that anal sex does not pose a risk for pregnancy in conjunction with the predominant view of condoms as a contraceptive method may leave some populations ignorant of the necessity of condom use during anal sex for STI and HIV protection.<sup>138</sup> Perhaps due to the HIV preventive focus on condom use for penile-vaginal sex, studies in India<sup>147</sup> and Kenya<sup>148</sup> assessing condom knowledge and use have found that men do not know HIV can be transmitted through anal sex and therefore, tend to not use condoms for anal sex. Other reasons people may not use condoms with anal sex are likely to be similar to those preventing condom use with penile vaginal sex, including fear of erection loss, lack of enjoyment, difficulty in obtaining condoms.<sup>113,149</sup>

## NOVEL INTERVENTIONS TO PROMOTE CONDOM USE

Perhaps the single best success story pertaining to the promotion of condom use comes from Brazil. In the early 1990s the AIDS epidemic in Brazil was not much different than the AIDS epidemic in other hard-hit countries. By the year 2000 AIDS incidence in Brazil had leveled off to about 25,000 cases per year,<sup>150</sup> less than one half the rate reported by the United States for 2006. In the short time between 1996 and 2002 Brazil achieved a 50% reduction in AIDS-related mortality and an 80% decline in AIDS-related hospitalization. Much of this public health success story is a direct consequence of an aggressive Brazilian political effort to promote condom use. Indeed, Brazil's national AIDS program has aggressively pursued the agenda of preventing HIV infection through a web of government programs, including widespread condom promotion campaigns utilizing state-of-the-art social marketing techniques (Fig. 11.1). These efforts exist in stark contrast to the lack of government support (and even opposition) for condom promotion in the United States. Similarly, Brazil has enjoyed great success promoting condom use among CSWs, a population that is blatantly ignored and marginalized in the United States.

In the early years of the AIDS pandemic, Thailand committed to an aggressive campaign designed to raise awareness of HIV/AIDS and to reduce risky behavior. The most well-known component of the program, the 100% Condom Policy, is designed to ensure condoms are used at all times in commercial sex

**Fig. 11.1:** This popular graphic in Brazil let the people know that nothing passes through a condom!

establishments. The policy is accompanied by a mass advertising campaign, by the distribution of free condoms to sex workers, and by a strong collaboration between local authorities, STI clinics, and all sex entertainment establishments.<sup>151–153</sup> Piloted in 1989 and implemented nationally in 1991,<sup>154,155</sup> the program is enormously successful and credited with preventing a 10-fold increase in HIV prevalence in Thailand.<sup>156</sup> The use of condoms with CSWs increased from 14% in 1989 to over 90% in 1992. The annual incidence of STIs nationally rapidly decreased from 400,000 cases per year prior to the campaign to less than 15,000 cases per year since 2000. Finally, the HIV prevalence in at-risk groups such as sex workers, STI patients, and pregnant women has steadily declined since program implementation.<sup>152,157</sup>

The campaign's success is due to a variety of factors, including the foresight and quick response of the Thai government.<sup>158</sup> Since the majority of the sex industry in Thailand and other Asian countries is brothel-based, this setting allows for the creation of a monopoly environment in which condom use is required and noncompliant sex work establishments may be penalized or closed.<sup>153,158,159</sup> Authorities are able to monitor condom use to some degree by tracking new STIs through an extensive network of STI clinics, routine examinations among sex workers, monitoring the number of condoms provided to sex work establishments, and by sending volunteers to test compliance.<sup>158,159</sup> Success is also due to penalizing noncompliant sex business owners, pimps, and customers rather than sex workers and to the fact that the policy bypasses economic and power differentials between sex workers and clients which can decrease effectiveness of STI/HIV prevention strategies relying on condom negotiation skills alone.<sup>153</sup> With guidance from the WHO,<sup>160</sup> variations of Thailand's 100% condom campaign have been instituted elsewhere in Asia, including Cambodia, Philippines, Vietnam, China, Myanmar, Mongolia, and Laos.<sup>152</sup>

Of note, a similar effort occurred recently in China, where a 100% condom use program (again, aimed at commercial workers) increased rates of condom use from 60% to 95% 12 months later, with corresponding decline in rates of chlamydia.<sup>161</sup>

In sub-Saharan Africa and in Asia, a systematic review of behavioral-based STI and HIV interventions suggests that the majority of preventive efforts directed at condom use are with partners in commercial sex or casual sex relationships. Further, substantial evidence indicates that the greatest increases in condom use have been achieved in these relationship contexts while interventions targeting youth or the general population were less successful or did not report significant changes in condom use.<sup>162</sup> One of the more successful youth-targeted interventions was delivered in Namibia; it offered training in communication and decision-making skills as supplement to HIV/AIDS education. As a result, youths participating in the intervention felt more capable of asking for condoms in clinics and of maintaining intimate relationships without having sex.<sup>163</sup> Overall, the most effective condom-use interventions reported using peer or other forms of health education, condom provision, and STI testing and treatment, suggesting that these three components may be very effective in combination. The review's findings are consistent across both sub-Saharan Africa and Asia.<sup>162</sup>

Other intervention attempts at increasing condom use take a structural approach intended to operate within economic, gender, and power frameworks in a society. For example, in South Africa, where 5.7 million people are living with HIV, the lack of development and economic opportunities in addition to persistent gender inequalities create an environment conducive to HIV risk. Structural interventions, such as the Intervention with Microfinance for AIDS and Gender Equity (IMAGE), work to positively change the social context and thereby influence multiple risk behaviors and health outcomes. IMAGE combines microfinance, a development tool that provides loans to people for income generation, with gender equity training and HIV education. During microfinance meetings, loan recipients participate in a 12–15 month training which addresses gender roles, cultural beliefs, relationships, communication skills, intimate partner violence (IPV), and HIV risks. The training further provides leadership opportunities for participants to mobilize their communities against issues such as IPV and HIV. Although the IMAGE intervention demonstrated increases in household economic well-being and women's empowerment and decreases in IPV, changes in sexual behavior, condom use, and HIV incidence were limited.<sup>164</sup> Long-term effects remain to be seen, but the integration of condom promotion into broader, structural-level programs is likely to continue in future prevention efforts.

Of course, government led and supported efforts to promote condom use represent a mere fantasy for STI prevention professionals in a vast number of countries. Thus, community-based and clinic-based programs have been tested for efficacy. Perhaps one of the best known and novel community-based approaches involves the use of popular opinion leaders.<sup>165</sup> In typical studies that use the popular opinion leader (POL) model, trained prevention specialists will identify key opinion leaders in a given community of persons being targeted for increased use of condoms. After being provided with extensive training, the selected opinion leaders begin to diffuse their condom

promotion messages to others in the community via face-to-face interactions. The model has been widely applied across different at-risk populations and in multiple countries.<sup>166</sup> Perhaps one of the best examples was reported by Kelly and colleagues.<sup>167</sup> In 1997 Kelly and colleagues published findings from the trial of a POL model applied in gay bars. Men attending gay bars in 8 cities were assessed as a barometer of program effectiveness. Compared to baseline assessments, the assessments made at the 1-year follow-up indicated a significant decline in unprotected anal intercourse (UAI) in the 4 cities that received the intervention program (from a baseline mean of 1.68 acts in the past 2 months to a 1-year mean of 0.59 acts,  $p = 0.04$ ).

An example of a novel, clinic-based, condom use promotion program is known as Focus on the Future.<sup>168</sup> This extremely brief program was predicated, in part, on the principle that effective behavioral intervention is contingent upon the careful development of culturally tailored approaches. The approach was based on five categories of condom-related issues identified from qualitative studies. These categories pertained to: (i) the “fit and feel” of condoms; (ii) condom brand and size; (iii) application problems; (iv) availability of condoms and lubricants; and (v) commitment to condom use. Collectively, these points suggested that men may use condoms more often if they could learn how to use them without feeling that they compromise the overall sexual experience. Thus, the unstated intent of the program was to “sexualize” condoms so that men would find them to be compatible with their goal of enjoying sex. A key part of this strategy was to provide men with a wide variety of condoms (including specialty condoms that are normally too expensive for many men to purchase) and to provide men with small plastic packages of water-based lubrication for condoms (in multiple flavors, scents, and colors). Much of the brief teaching session (conducted using a one-to-one format by a lay health advisor) was devoted to letting men learn about condom brands and sizes, letting them practice condom application of penile models, and giving them instruction on the value and use of lubricants. Compared to men randomized to a control condition, those receiving the intervention were significantly more likely to report using condoms at last sex episode (72.4% vs. 53.9%,  $p = 0.008$ ) and they reported fewer acts of unprotected sex (mean of 12.3 vs. 29.4,  $p = 0.045$ ).<sup>168</sup> This type of program (brief and clinic-based) may have a great deal of utility as it can easily be incorporated into the everyday practice of STD clinics. For skeptics arguing that implementation of even brief clinic-based condom promotion program require hiring a staff member (i.e., a health educator), it is worth noting that a recent pilot study has found promising results from a self-guided home-based intervention program designed for young men.<sup>169</sup> A central aspect of this intervention approach was to provide young men with a “prescription” for individual practice, designed to enhance condom use skills, comfort, and confidence in a situation where the performance pressure inherent in partnered sex should be attenuated. In this self-guided intervention, young men were provided with brief instructions on condom use and the opportunity to use a variety of condoms and lubricants to

allow them to discover the optimal products for their needs. The research team found significant increases in participants' sexual sensation during condom use, their reported levels of comfort using condoms, and their self-efficacy for condom use. Further, they found significant reductions in reported problems with the "fit and feel" of condoms, a variable that has been a fairly robust predictor of condom breakage.<sup>111,113,114</sup> Significant increases were also observed relative to adding water-based lubricants to condoms and a significant decrease in condom-associated erection loss was observed.

## Condoms and Politics

Promoting the use of condoms for STI and HIV prevention is futile if condoms are not readily available. Indeed, the lack of access to condoms still remains a significant barrier to STI/HIV prevention today. In most countries, condom availability results from a combination of government, private sector, and nonprofit efforts; these efforts are frequently supported by the United Nations Population Fund (UNFPA; the United Nations agency responsible for providing condoms) which integrates the provision of condoms as a component in its broader HIV prevention program. Despite these combined efforts, data from the UNFPA suggest that condom shortages frequently occur. In 2004, the provision of 2.1 billion condoms by bilateral donors, the UNFPA, and social marketing organizations to sub-Saharan Africa only stretched to about 10 condoms per man of reproductive age.<sup>68</sup> Earlier research found that sub-Saharan African countries providing the most condoms still averaged only about 17 condoms per man; 1.9 billion more condoms would be needed in order to replicate that level of provision for other sub-Saharan African nations.<sup>170</sup> The shortage of condoms often creates inefficiencies in other aspects of STI/HIV prevention. For example, an evaluation of condom distribution in Sao Paulo, Brazil, found that regular condom shortages influenced the management of available condom resources. Distribution became based on "first-come, first-serve" basis, such that condoms were not distributed with any epidemiologic impact and were not distributed actively.<sup>171</sup> Finally, in many resource-poor nations, condoms often come at the cost of other national needs; the purchase of condoms not covered by donations may take government funds from food, medicine, and other necessities.<sup>68</sup>

Even when condoms are available, there are a number of factors which may affect their accessibility. Condoms are often provided for free in public clinics; however, there is evidence that condoms offered for free are viewed as old or of inferior quality.<sup>172</sup> Regularly purchasing condoms available in the commercial sector may prove expensive for some people although research among adolescents in urban Cameroon determined that free and commercial distribution programs can effectively complement each other. In this study, sexually inexperienced youth were more likely to be reached by free condom programs while sexually experienced youth showed higher rates of condom use and fewer wasted condoms with condoms purchased from commercial programs.<sup>173</sup> Additionally, condoms provided freely by government or donor

agencies may not represent the variety in size, fit, and style represented in the commercial sector. A randomized controlled trial among men in Jamaica testing the impacts of variety in condom choice found that choice increased men's perceived sexual pleasure with condoms but did not impact their level of condom use or STI incidence.<sup>174</sup> In contrast, qualitative research conducted among African American men in the southern United States emphasized that men experienced problems with the "fit and feel" of free condoms available at clinics.<sup>112</sup> Clearly, condoms of appropriate size, fit, and monetary cost are not always readily accessible.

Additionally, there are other costs associated with condom accessibility; for example, in some areas in South Africa, access to condoms involves substantial travel time and travel costs to distribution sites.<sup>175</sup> Research investigating access to condoms in rural Tanzania found people usually had to walk 3–10 kilometers before reaching the government health facilities distributing condoms.<sup>172</sup> Researcher attempts to access condoms from public health clinics in Kwa-Zulu Natal, a region in South Africa with a concentrated HIV/AIDS epidemic, found that although clinics were accessible by walking, nearly all were poor or inadequately signed. Furthermore, the clinic hours of operation were limited to business hours during the weekdays, and some clinics restricted the hours in which condoms were distributed.<sup>176</sup> Such barriers may have particular impact on at-risk populations such as adolescents who are in school during clinic or condom distribution hours.<sup>176,177</sup> Evidence from Zambia also suggests that condom access may differ across sociodemographic characteristics as well. Study findings suggested that poorer men had greater access to condom outlets within their neighborhood while wealthier men had fewer opportunities to access condoms nearby.<sup>178</sup>

Further costs in accessing condoms may include the social stigma, embarrassment, and judgmental or hostile attitudes of providers. Qualitative work in the United Kingdom suggests that embarrassment and fear of judgment is a key barrier to adolescents accessing condoms, STI/HIV information, and sexual health advice.<sup>179</sup> Both condom providers and customers in Tanzania reported embarrassment in interactions regarding the exchange of condoms or questions about condoms. Customers also believed that health workers and condom distributors would not keep such exchanges confidential or private.<sup>172</sup> The lack of a private space in which to purchase or gain instruction in the application of condoms has also been reported as a barrier to accessibility elsewhere.<sup>176,179</sup> These studies in settings as diverse as the UK and Tanzania suggest that the need for privacy and anonymity is heightened in rural areas where populations are small and the disapproving scrutiny or gossip from others may be overwhelming.<sup>172–179</sup>

There is also a gender component to condom accessibility which may serve as barriers to both sexes. Family planning clinics, for example, generally target female clientele and this has frequently fueled the perception that services, including the provision of condoms, are not available for men. The female focused environment at family planning clinics can also deter

men from feeling comfortable enough to seek condoms at these locations.<sup>180</sup> Conversely, social attitudes may make condom provision to males more acceptable than to females. A South African study found male research staff attempting to access condoms at a variety of locations received more attention and information than their female counterpart. Male research staff members were provided with more demonstrations in how to use condoms while female research staff recorded instances in which condom providers refused to provide condom use instructions or condom-related consultation with a physician.<sup>176</sup>

The attitudes and opinions of various parties as well as the political climate may influence condom availability and accessibility in a region. The provision of condoms to adolescents is one such example since this issue generally creates social division wherever considered. Many people believe the availability of condoms to adolescents endorses adolescent sexual behavior and causes increases in adolescent sexual activity<sup>181–183</sup> although empirical research has proven otherwise.<sup>184–186</sup> Others cite moral concerns in their argument against condom promotion, stating that it will undermine the preservation of traditional values such as abstinence until marriage.<sup>177</sup> Proponents of condom provision for adolescents may argue that adolescent sexual activity is inevitable and youth should be provided with means to protect themselves from infection.<sup>185</sup> The mix of these opinions and their impact on health policy in an area can heavily impact the availability of condoms for youth.

## Female Condoms

In 1993, the United States Food and Drug Administration (FDA) approved the first version of the female condom (FC1) as a barrier contraceptive providing limited protection against STIs. FC1 consists of a lubricated polyurethane sheath with two flexible rings (one attached and one unattached). Similar to a diaphragm the ring at the closed end of the device is inserted into the vagina (protecting the cervix), while the ring at the open end remains outside the vagina partially covering the labia. The FDA approved a second version of the female condom (FC2) for US marketing in March 2009. This new version is made of nitrile, a material less expensive than polyurethane.

The United States Centers for Disease Control (CDC) and the FDA continue to recommend the use of female condoms as an effective alternative mechanical barrier to viruses when male condoms cannot be used. This conditional recommendation reflects that while laboratory studies indicate that the female condom provides protection from STI pathogens,<sup>187</sup> only a limited number of applied studies have assessed the effectiveness of female condoms in preventing STIs.<sup>188–191</sup> While continued research in this area is necessary and continues to be encouraged by the CDC, the WHO, United States Agency for International Development (USAID), and other global health organizations, it is important to focus on the fact that female condoms are an alternative barrier method that confer similar protective values as male condoms when

used consistently and correctly and under some circumstances female condoms may be the only option for protection for women at risk of contracting HIV.

Female condoms allow women more control over the use of a barrier method contraceptive. This advantage is particularly important as a means of protection against STIs, including HIV for women in situations where their male partners refuse or are reluctant to use male condoms. Numerous socioeconomic, cultural, and historic factors promote a global environment where women are particularly at risk for contracting STIs, including HIV.<sup>192</sup> Around the world women are increasingly at risk for HIV/STIs through heterosexual contact.<sup>193,194</sup> Thus, for many women female condoms provide an opportunity for self-protection under circumstances of limited power. Additional benefits of the female condom include: (i) individuals allergic to latex can use them; (ii) both water based and oil based lubricants can be used; (iii) they do not require a prescription or fitting; and (iv) they do not require a penile erection (Planned Parenthood).

While female condoms have many advantages, some prominent disadvantages of this method should be noted. Cost is one of the most obvious disadvantages and barriers to use. This problem led to investigations on whether the FC1 device could be used multiple times. In 2002, the WHO issued a statement on reuse of FC1, which did not recommend reuse of the device but provided a draft protocol for handling and preparation for reuse.<sup>195</sup> This decision was based on the complex contextual factors that at times make weighing the risks and benefits of reusing FC1 a decision to be made locally. The FC2 is 30% less expensive than the FC1, but these new female condoms are still 15–20 times more expensive than male latex condoms and approved for one time use only.<sup>196</sup>

Other disadvantages of female condoms include the following: (i) some individuals experience irritation of the vagina, vulva, or penis; (ii) slippage of the device into the vagina may occur; (iii) unpleasant or distracting noises have been reported with use of FC1; and (iv) similar to male condoms individuals report reduced feelings during intercourse.<sup>197</sup> Additionally, female condoms are detectable by male partners, and negotiating their use with partners already opposed to male condom use and suspicious of female infidelity may be difficult for women.<sup>198</sup>

There is a dearth of studies assessing the direct effectiveness of female condoms in the prevention of STIs. A larger body of research has focused on general awareness and use of female condoms.

An important question for health researchers working in HIV and STI prevention is whether female condoms are actually being accepted and used by women and their sex partners around the globe. Studies examining the general acceptability and use of female condoms suggest that general use remains limited. One study examining HIV prevention strategies other than male condoms among low-income heterosexually active women found that 16% of the 1469 women expressing an HIV/STI prevention method preferred the female condom.<sup>199</sup>

In another study, examining female awareness and use among female Nigerian college students, researchers found 11.3% of

850 women had ever used the female condom.<sup>200</sup> These female condom users reported using the female condom to: (i) prevent unwanted pregnancy and STIs including AIDS (40%); (ii) to prevent pregnancy only (27.1%); and (iii) to prevent STIs including HIV only (19.8%). Interestingly, almost half (47%) of the women using female condoms reported their sex partners approved of using it.

Studies have also investigated potential markers of female condom use. Similar to male condom use, partner type tends to play a role in the use of female condoms. For example, a study of inner city African American women ( $n = 280$ ) found women with multiple sexual partners were 5 times more likely to use female condoms than women in a monogamous relationship.<sup>201</sup> Furthermore, a study conducted after a social marketing campaign in Zimbabwe ( $n = 1740$ ) found variables associated with consistent use among males and females differed between individuals with marital and nonmarital partners.<sup>202</sup> Variables associated with consistent use among individuals with marital partners suggests female condoms are used for pregnancy prevention alone, while variables associated with consistent use with nonmarital partners suggests female condoms are used for both pregnancy and STI prevention.

While general use of female condoms remains limited, behavioral interventions promoting use and acceptability of the device suggest that under some circumstances female condoms remain at the very least an additional option for STI, including HIV protection for some women. This has been particularly true for those women most at risk for contracting STIs.<sup>203–207</sup> These early interventions were delivered to a wide range of samples and utilized various prevention activities to promote behavior change.

Findings from more recent randomized control trials suggest female condoms may still be a viable option for protection, and behavioral interventions can increase use and acceptability. For example, a small-group skills training intervention delivered to women with risk factors (e.g., a diagnosed STI, multiple sex partners, IDU, or a high risk sex partner) found at the 3-month follow-up that 59.9% of intervention participants compared to 21.9% of control group participants used the female condom at least once.<sup>208</sup> Another study compared an 8-session and 4-session group counseling intervention to an assessment only control and found first-time female condom use was increased in the 8-session intervention compared to the 4-session intervention, and in the 4-session intervention compared to the control group.<sup>209</sup> In yet another randomized trial that compared participants in a female condom skills training to those in a general health promotion group, results indicated that at both the 3-month and 6-month follow-up participants in the intervention were more likely to have used the female condom than those in the control group.<sup>210</sup>

Most interventions have focused on female participants alone; however, a recent intervention focused on heterosexual couples. Couples were assigned to one of three conditions: (i) a 6-session relationship-based intervention for the couples together; (ii) the

same intervention delivered to women alone; or (iii) a women's only control group receiving a one-time education session.<sup>211</sup> While there were no significant differences in female condom use between the two intervention groups at the 90-day follow-up, participants in both intervention groups were more likely to have used a female condom than control group participants. Intervention participants also reported being more likely to intend to use female condoms in the next 90 days than the control group.

These recent studies, as well as earlier literature suggest behavioral interventions can, in fact, increase use of female condoms, at least in the short term. These studies also highlight some other interesting points about promoting female condom use. First, interventions should include counseling on both information and skills based training (including self-insertion practice).<sup>208–210</sup> Second, those promoting female condom use may want to continue exploring couples-based interventions.<sup>211</sup> Finally, interventions promoting female condom use do not necessarily decrease male condom use.<sup>210</sup> Promoting female condom use can create an environment where mixing the use of female and male condoms ultimately leads to more consistent condom use for women most at risk of contracting STIs, including HIV.<sup>203,206</sup>

## Other Barrier Methods—Diaphragms and Cervical Caps

Diaphragms are a female controlled contraceptive method that can be used in many circumstances without a male partner's detection. The device is a latex cup inserted into the vagina prior to sexual intercourse, and it requires an examination and a prescription. As a contraceptive device, it is traditionally used in conjunction with spermicide. A recent study comparing contraceptive efficacy between use of the diaphragm alone and with spermicide was unable to confirm efficacy of the diaphragm alone.<sup>212</sup> This is somewhat troubling considering the use of spermicide is discouraged for women at risk for STIs including HIV. With this said, researchers concerned with the lack of choices women have to protect themselves from increasing rates of heterosexual HIV transmission are proposing the diaphragm as an alternative method of HIV protection.<sup>213,214</sup>

The diaphragm is a device that protects the cervix, and limited observational studies offer some evidence that the diaphragm offers protection from STI pathogens including gonorrhea.<sup>214</sup> As studies are underway investigating the actual efficacy of the device, other researchers have begun the process of exploring the acceptability of diaphragms.<sup>215–217</sup> These acceptability studies suggest barriers to use exist, but some women will be open to using the diaphragm as an additional means of protection if and when its efficacy as a form of HIV prevention is clear.

Similar to the diaphragm, cervical caps are another female controlled barrier contraceptive. Instead of latex, cervical caps are made of silicone and they too require an examination and prescription. Like the diaphragm women can insert cervical caps prior to sexual intercourse and a male partner unwilling to use protection from STIs can often not detect them.<sup>218</sup>

Clearly additional research is needed to confirm the STI protective value of barrier devices such as the diaphragm and cervical caps, but early research suggests if and when their protective value is confirmed these devices can be another option for protection for women most at risk for STIs including HIV. Additional studies will also need to consider how diaphragms and cervical caps can be combined with vaginal microbicides to offer women increased protection.

## Vaginal Microbicides

Globally, perhaps the greatest single hope for a reduction in AIDS rests on the premise that women (and perhaps willing male partners) will insert chemical products into the vagina before sex occurs in order to destroy HIV if it is present in the ejaculate. Like all biochemical innovations, the successful use of vaginal microbicides will require behavioral intervention (i.e., education, skill acquisition, and access to the product). Unfortunately, only a few behavioral studies have focused on men. This is attributable to the original intent of microbicide development, i.e., to provide women with a clandestine method for preventing HIV. However, as microbicide research advances it has become clear that women may indeed want and even need to include their male sex partners in the use of microbicides.<sup>219,220</sup>

Although studies of women suggest that enhanced intimacy and trust are primary motivations for involving men, it should also be recognized that mutual action may aid in the correct use of microbicides. Just as condoms are frequently used incorrectly, great potential for user error also exists with microbicides. Recent evidence suggests that condom use errors and problems are reduced when condom use is a mutual decision<sup>120</sup> and this same phenomenon may apply to microbicides. Moreover, studies of men suggest that they may indeed be supportive of couple-based decisions regarding microbicide use as long as sexual pleasure is not compromised.<sup>221,222</sup> A primary concern of men appears to be the excessive “wetness” that will inevitably occur with application of the 3.5 ml of gel. As described in one research article, microbicides might become widely used if they do not substantially lubricate the vagina.<sup>221</sup> This point is critical because it is now clear that the likely carrier for a successful microbicide will be a gel and therefore “substantial lubrication” of the vagina is inevitable. Moreover, the scientific community is well aware that poorly lubricated vaginal tissue is far more susceptible to abrasion thereby magnifying risk of HIV transfer. Thus, one important behavioral question that must be immediately addressed is, “How can men be motivated to consistently accept the presence of a gel added to the vagina during heterosexual intercourse?”

A second question is equally important: “Will men replace condom use by use of microbicides?” This question has not been studied extensively; however, several mathematical modeling analyses have suggested that extensive condom replacement would need to occur before the overall public health benefit of a relatively effective microbicide would be negated.<sup>223,224</sup> The mathematical modeling exercises are flawed, unfortunately, in that they do not consider the prevalence and effect of common STDs (e.g., chancroid, syphilis,

chlamydia, genital herpes, trichomoniasis, and HPV) on either microbicide efficacy or susceptibility to HIV acquisition. Indeed, current evidence suggest that a “healthy vagina” (i.e., disease free, including lack of bacterial vaginosis) is a prerequisite to optimal microbicide effectiveness.<sup>225</sup> Rates of condom replacement may also vary widely by age, with young men potentially being more likely to forgo condoms given the introduction of microbicides. It is now widely apparent that the first generation of microbicides will need to be introduced in conjunction with efforts to promote and sustain condom use.<sup>226</sup> In essence, this simple observation necessitates male partner involvement and requires the application of efficacious (but brief) teaching protocols shown to promote men’s consistent and correct use of condoms.

### Summary

Barrier methods of STI prevention are vital tools for controlling the spread of epidemics worldwide. In particular, condom use is the primary method of prevention. Given adequate attention to the promotion of both the consistent and the correct use of condoms, this method can greatly mitigate the spread of STIs. Ongoing behavioral research regarding how best to achieve this promotion is needed across all at-risk populations. Like so many other aspects of public health, the promotion of condoms will be greatly facilitated by the support of local governments; doing so is vital to STI prevention. The use of female condoms, cervical caps, and diaphragms also represents a valuable set of prevention methods, with each having unique advantages and with each involving challenges that can be met through creative promotion approaches. Finally, the prospect for future approval and use of vaginal microbicides warrants immediate behavioral research.

# Prevention of HIV and other Sexually Transmitted Infections: Male Circumcision

# 12

Natasha L. Larke • Helen A. Weiss

## Introduction

Three randomized controlled trials (RCTs) in sub-Saharan Africa have shown that circumcised men are at reduced risk of HIV infection. In this chapter we review the evidence that male circumcision reduces risk of HIV and other sexually transmitted infections (STIs), and discuss current research and public health implications of the findings for HIV transmission.

## Background

Male circumcision is the surgical removal of the prepuce, or foreskin, of the penis. It is one of the oldest and most common surgical procedures performed worldwide, with approximately 30–35% of men circumcised worldwide.<sup>1</sup> Circumcision is practiced for religious, social, and medical reasons. Overall, approximately two-thirds of circumcised men are Muslim, with coverage almost universal in the Middle East, North Africa, Pakistan, Bangladesh, and Indonesia. Circumcision is also practiced for nonreligious reasons either neonatally or as a rite-of-passage to manhood and is very common in West Africa, parts of Central and Eastern Africa, the United States, Republic of Korea, and the Philippines.<sup>1</sup> Within countries, prevalence can vary widely with religion, ethnicity, and socioeconomic status. For example, in Kenya, circumcision is almost universal in most ethnic groups, but has traditionally been uncommon among the Luo, who reside mainly in western Kenya.

The age at which circumcision is undertaken is determined by sociocultural and religious traditions, and it may occur from the neonatal period to early adulthood. Cultural attitudes toward circumcision can change over time, and there have been rapid increases and decreases of prevalence in several settings among non-Muslims and non-Jews, which may result from increased mixing between different cultures, religions, and socioeconomic groups, or from changes in perceptions of health or sexual benefits associated with the practice.<sup>1</sup>

## Biological Evidence for a Protective Effect of Circumcision on HIV/STIs

There are several mechanisms by which the presence of the foreskin may increase a man's risk of acquiring STIs, including HIV. The warm, moist environment under the foreskin favors pathogen survival and replication, as shown by recent data from Uganda where, following circumcision, men had fewer proinflammatory anaerobic bacteria.<sup>2</sup> These bacteria may exacerbate existing infection and increase risk of genital ulcer disease (GUD) in uncircumcised men. Further, unlike the glans penis and the outer surface of the foreskin, the inner mucosal surface of the foreskin is thinly keratinized<sup>3</sup> and hence susceptible to minor trauma and abrasions which facilitate entry of pathogens.<sup>4</sup> Finally, lesions and ulcers produced by STIs may be less well-detected and treated in uncircumcised men.

An increased risk of GUD in uncircumcised men provides a potential pathway for increased risk of HIV, through the disrupted mucosal surface. In addition, the foreskin is likely to increase the risk of HIV infection specifically as tissue from the inner surface of the foreskin mucosa contains higher proportions of HIV-1 target cells than cervical tissue.<sup>5</sup> Further, the HIV-1 target cells in the inner foreskin are closer to the epithelial surface than those situated elsewhere in the penis, due to the lack of keratin,<sup>3</sup> and are more easily infected during exposure to vaginal secretions. In contrast, in circumcised men, the penile shaft is thought to be covered with a thickly keratinized epithelium, providing some protection from infection.<sup>3</sup>

## Epidemiological Evidence for a Protective Effect of Circumcision on HIV/STIs

### ASSOCIATION BETWEEN MALE CIRCUMCISION AND RISK OF HIV INFECTION IN HETEROSEXUAL MEN

The hypothesis that male circumcision might protect against HIV infection was first suggested in 1986<sup>6,7</sup> and was subsequently supported by ecological studies showing correlation between areas

of low prevalence of male circumcision and high HIV prevalence in sub-Saharan Africa in the late 1980s,<sup>8,9</sup> and, later, across 118 developing countries.<sup>10</sup>

A systematic review and meta-analysis of 27 studies from sub-Saharan Africa was published in 2000,<sup>11</sup> showing that circumcised men were at significantly lower risk of HIV infection after adjusting for potential confounding factors (adjusted risk ratio [RR]=0.42, 95% confidence interval [95% CI] 0.34–0.54). A subsequent systematic review published in 2005 confirmed these findings.<sup>12</sup> However, observational epidemiological studies are inherently limited by potential biases and cannot provide conclusive evidence that circumcision reduces risk of HIV infection. Researchers therefore initiated three RCTs of circumcision among adult men in 2002–2003, to investigate the potential association more rigorously.

These trials recruited men willing to be circumcised in traditionally noncircumcising communities in Uganda, Kenya, and South Africa. In total 10,908 men were randomized to be offered immediate circumcision (intervention arm) or circumcision at the end of the trial (control arm), and were followed-up for up to 2 years to compare HIV incidence in the two arms. Trial characteristics are shown in Table 12.1.<sup>13–15</sup> In all 3 trials, an independent Data and Safety Monitoring Board recommended the trial be stopped early as higher HIV incidence was seen among men randomized to the control arm. Overall, men randomized to the circumcision arm were at approximately 60% less risk of becoming HIV infected during the trial than men in the control arm, a finding consistent with that observed in the observational studies (Fig. 12.1).<sup>16,17</sup>

Following publication of the trial results in early 2007, the World Health Organization and the Joint United Nations Programme for HIV/AIDS organized an international consultation of researchers and stakeholders to discuss the implications of these findings. The participants concluded that there was compelling evidence that male circumcision partially reduced the risk of HIV acquisition, and that promotion of male circumcision should be included as an additional HIV strategy for the prevention of heterosexually acquired HIV infection in men.<sup>18</sup>

**Table 12.1:** Summary of Three Randomized Controlled Trials of Male Circumcision on HIV Acquisition in Sub-Saharan Africa

	South Africa	Uganda	Kenya
Trial setting	Semi-urban	Rural	Urban
Background HIV incidence	~3–5/100 person years	~1.5/100 person years	~2.5/100 person years
Age range	18–24	15–49	18–24
Surgeons	General MDs	Medical officer	Medical officer
Surgical method	Forceps guided	Sleeve	Forceps guided
Number of men (final)	3520	5000	2800

Taken from (Weiss, Halperin et al. 2008)<sup>16</sup>

**Fig. 12.1:** Random-effects meta-analysis for the randomized controlled trials with summary risk ratio for the observational data.

## ASSOCIATION BETWEEN MALE CIRCUMCISION AND RISK OF HIV INFECTION IN HETEROSEXUAL WOMEN

A fourth RCT was conducted in Rakai, Uganda, to evaluate the impact of male circumcision on HIV acquisition in women. In this trial, 922 HIV-infected men were randomized to either immediate or delayed circumcision.<sup>19</sup> The men were aged 15–49 years old, asymptomatic, and with CD4 counts of 350 cells/ $\mu$ L or more. A total of 163 uninfected female partners were enrolled at the same time as the men, and followed for up to 24 months. However, the trial was stopped early due to the small number of female partners enrolled at the same time as the men. Over the 24 month follow-up period, 22% of the females in the intervention arm seroconverted compared with 13% in the control arm (hazard ratio=1.58, 95% CI 0.68–3.66). This study therefore provides no evidence that circumcision protects against male-to-female HIV transmission. Further, there was some evidence that recently circumcised HIV-positive men who resumed sexual activity early may be more likely to transmit HIV in the first 6 months after surgery than those who wait until complete wound healing, but these numbers are too small to be conclusive. Among the 18 couples in the intervention arm who resumed sex more than 5 days before certified wound healing, there were 5 seroconversions (27.8%), compared with 6/63 seroconversions (9.5%) among those who first had sex after this time ( $p=0.06$ ). This latter figure is similar to the seroconversion risk among couples in the control arm (6/68; 8.8%).<sup>19</sup>

Although there may be no direct impact of circumcision on male-to-female transmission, there will be an indirect benefit to women if expanded circumcision services reduce HIV prevalence in their male partners. Mathematical modeling shows that these benefits will likely take several years to become evident, and

will increase over time, with subsequent reductions in rates of mother-to-child transmission.<sup>20</sup>

### ASSOCIATION BETWEEN MALE CIRCUMCISION AND RISK OF HIV INFECTION IN MEN WHO HAVE SEX WITH MEN

The implications of the trial findings for men who have sex with men (MSM) are unclear. HIV transmission from penile-anal intercourse is predominantly to the receptive partner<sup>21</sup> a risk unlikely to be directly modified by his circumcision status. However, it is biologically plausible that male circumcision provides partial protection against HIV acquired through insertive anal intercourse, as it does for vaginal-penile intercourse. There have been no RCTs of circumcision among MSM, but a meta-analysis of 18 observational studies conducted worldwide found little association of male circumcision with HIV infection (OR=1.02, 95% CI 0.83–1.26).<sup>22,23</sup> The message for all men, regardless of sexual orientation or circumcision status, is that practicing safer sex behaviors, including correct and consistent condom use, is the best way to avoid infection.

### ASSOCIATION BETWEEN MALE CIRCUMCISION AND RISK OF OTHER SEXUALLY TRANSMITTED INFECTIONS

The RCTs also provide data on the association between circumcision and STIs (Table 12.2). In general, the associations seen are weaker and less consistent than the findings for the association with HIV infection. The trials from Uganda and South Africa indicate that men in the circumcision arm had around 30% less risk of acquiring HSV-2 (adjusted hazard ratio (HR) 0.72, 95% CI 0.56–0.92 in Uganda and 0.68, 95% CI 0.38–1.22 in South Africa).<sup>24–26</sup> The Ugandan trial has reported no impact on serological syphilis, (adjusted hazard ratio 1.14, 95% CI 0.77–1.75), but significant reduction in the incidence of HSV-2 and HPV infection<sup>26</sup>. The risk of self-reported GUD was significantly lower among circumcised men in the Kenyan trial (RR = 0.53), and among both HIV positive and HIV negative

men in the Ugandan trials (RR = 0.63, 95% CI 0.5–0.8 and 0.54, 95% CI 0.46–0.66, respectively).<sup>27,28</sup>

The trials have also provided data on the association of circumcision with nonulcerative STIs (Table 12.2). The strongest effect of circumcision was observed on *Trichomonas vaginalis* prevalence in the South African trial, where circumcised men were less likely to be infected at the final follow-up visit compared to uncircumcised men (adjusted odds ratio 0.47, 95% CI 0.25, 0.92),<sup>25</sup> although a weaker effect on *Trichomonas vaginalis* incidence was seen in the Kenyan trial.<sup>29</sup> A reduced risk of *Trichomonas vaginalis* in female partners of circumcised men was also seen in the Ugandan trials of both HIV positive and negative men, as well as a reduced risk of bacterial vaginosis in female partners of HIV negative, but not positive, men.<sup>19,30</sup> There is relatively little evidence of an effect of circumcision on *Chlamydia trachomatis* in the trials,<sup>25,29</sup> and no impact on *Neisseria gonorrhoeae*.<sup>25,29</sup>

Finally, a strong effect of circumcision was also observed on the prevalence of human papillomavirus (HPV) at the final follow-up visit in both the Ugandan and South African trials.<sup>26,31</sup> In both trials the prevalence of high-risk HPV (HR-HPV) isotypes was approximately 30–35% lower in the circumcised arm compared to control arm. A meta-analysis of observational studies also found that circumcised men were at significantly lower risk of HPV (OR=0.52, 95% CI 0.33–0.82).<sup>32</sup> A lower risk of HPV prevalence among circumcised men could indicate that circumcision decreases either HPV incidence, or increases clearance rates, and further work is needed to elucidate these findings. A randomized trial found reduced prevalence and incidence of high risk HPV in the female partners of circumcised men,<sup>33</sup> and by implication lower risks of cervical and penile cancers.

The Ugandan trial reported greater efficacy on HIV among men at higher risk (those with nonmarital sexual partners, reporting transactional sex or having a history of genital ulcers); i.e., about 75% risk reduction. A similar observation was seen in the earlier meta-analysis of observational data (adjusted RR=0.29, CI 0.20–0.41). A stronger protective effect in high risk groups may be due in part to circumcision protecting against other STIs, thus providing additional indirect protection against HIV. However, models indicate that a relatively small proportion of the impact of circumcision on HIV is mediated through GUD or other STIs. Models based on the Kisumu data estimate that about 10–20% of the HIV infections prevented by male circumcision were due to efficacy against STIs.<sup>34</sup>

**Table 12.2:** Impact of Male Circumcision on STIs in Men

STI	Outcome measure	Trial	RR	95% CI
HSV-2	Incidence	South Africa	0.66	0.39–1.12
		Uganda	0.72	0.56–0.92
<i>N. gonorrhoeae</i>	Prevalence	South Africa	0.94	0.69–1.29
	Incidence	Kenya	0.95	0.68–1.28
<i>Chlamydia trachomatis</i>	Prevalence	South Africa	0.56	0.32–1.00
	Incidence	Kenya	0.87	0.65–1.16
<i>Trichomonas vaginalis</i>	Prevalence	South Africa	0.53	0.28–1.02
	Incidence	Kenya	0.77	0.44–1.36
HPV	Prevalence	South Africa	0.66	0.51–0.86
		Uganda	0.65	0.46–0.90
Syphilis	Prevalence	Uganda	1.14	0.77–1.75

### Scale-up of Male Circumcision for HIV Prevention

Following the recommendations by WHO/UNAIDS in 2007,<sup>18</sup> several countries in southern and eastern Africa are introducing or expanding safe male circumcision programs, with funding from international donors. These include operational research studies to monitor key programmatic issues including the safety

of the procedure, counseling to minimize risk compensation (i.e., increased unprotected sex among circumcised men who feel they have an “invisible condom”), impact on sexual function and satisfaction, and methods to match supply and demand of circumcision. For example, studies on the impact of circumcision on sexual function have been conducted in the trial settings, and in Uganda very high levels of satisfaction (>98%) were reported in both arms of the trial and in Kenya reported sexual dysfunction decreased during the trial and were similar in the two arms.<sup>35,36</sup>

One of the major concerns about the expansion of circumcision services is the safety of the procedure. Common complications include bleeding, wound infection, and swelling. Adolescent or adult circumcision is a more complex procedure than when performed in infants, requiring suturing. In the three RCTs, complications were observed in 3–7% of HIV-negative men,<sup>13,37,38</sup> and in 6–8% of HIV positive men.<sup>13,38</sup> The majority of these were mild. In the Rakai trial safety increased with number of surgeries performed by the physician, where complications occurred in ~9% of procedures for the first 20 procedures declining to under 4% thereafter. Furthermore, physicians in the trials were provided with training, supervision, and adequate resources and this is likely to have contributed to the low complication rate in comparison to other settings.<sup>38</sup> There is scope for a higher risk of complications outside of trial settings. A systematic review of circumcision complications among men in Anglophone Africa showed that prevalence of complications varied widely (from 0% to 24%). Most of these were minor, but these risks are still a cause for concern.<sup>39</sup> Circumcision conducted by nonclinical providers can be associated with very high complications, as seen in a study among 562 adolescents from the Babukusu ethnic group in western Kenya, which found that 18% of men had a complication when the procedure was performed by a medical provider and when the procedure was performed traditionally the complication risk was 35%.<sup>40</sup> A sub-study in the same population directly observed 24 boys undergoing medical and traditional circumcision, respectively, and found that some boys experienced permanent adverse sequelae, including one very serious life-threatening case by a “medical” practitioner who was later found to have no documented medical qualifications. These results show that under nonsterile conditions, adolescent and adult circumcision can frequently be associated with severe complications.

National policies are needed to ensure the provision of adult male circumcision services which can be provided safely and efficiently, and WHO/UNAIDS have produced guidelines on provision of safe circumcision.<sup>41</sup> Neonatal or infant circumcision is a simpler and safer procedure than adult circumcision and therefore countries may choose to also expand services among younger boys as a longer-term HIV prevention strategy.

There are also concerns that risk compensation may occur following the expansion of circumcision services, where unsafe sexual practices among men increase, due to a belief they are protected from HIV infection. However, mathematical modeling suggests that considerable increases in risky behavior would be

required to override the protective effect of circumcision.<sup>42</sup> In the trials, there were few differences in reported sexual behavior by circumcision status<sup>13–15</sup> but these may not reflect patterns of behavior change during scale-up of circumcision for several reasons. Firstly, men enrolled on the trial were not aware that circumcision reduced the risk of HIV. Furthermore, the capacity to provide high quality behavioral counseling outside a trial setting will be challenging in already overstretched health services. Results from one study conducted outside a trial setting are promising: of 648 men from Western Kenya, those who elected to be circumcised reported similar risky sexual behavior following the procedure compared to men who remained uncircumcised.<sup>43</sup> However, this study was published prior to the results of the RCTs and further observational studies are needed in the current era to fully evaluate the potential issue of risk compensation. Further work to evaluate optimal counseling strategies in resource-poor settings is ongoing.

As a one-off procedure requiring no ongoing user-adherence, male circumcision is likely to be a cost-effective HIV prevention strategy.<sup>42,44</sup> For example, in the Gauteng Province, South Africa, where HIV prevalence is 25.6%, and the majority of men are currently uncircumcised, it is estimated to cost US\$181 per HIV infection averted, assuming all men were circumcised.<sup>44</sup> Ultimately this could save US\$2.4 million net over 20 years considering the costs averted through a decline in HIV incidence. In Rakai, Uganda, where HIV incidence is lower, authors estimated it would cost US\$2631 per HIV infection averted assuming 75% of males were circumcised.<sup>42</sup>

## Conclusions

Male circumcision is the only intervention to have proven efficacy against HIV infection in multiple RCTs. However, this protection is only partial (approximately 60%) and access to safe circumcision services accompanied by comprehensive behavioral counseling is needed. Further operational research is ongoing in southern and eastern Africa to identify the best method of integrating safe circumcision services into current health systems, as well as the development of relevant counseling materials.

## Microbicides for Prevention of Sexually Transmitted Infections

G.P. Talwar • Kavita B. Garg

### Introduction

According to World Health Organization (WHO),<sup>1</sup> 480 million new cases of sexually transmitted infections occurred in the year 2005 around the world, in addition to HIV which was transmitted to about 2.7 million humans.<sup>2</sup> *Neisseria gonorrhoeae* accounted for around 87 million and Chlamydia for more than 101 million infections. Human papillomavirus (HPV) leading eventually to carcinoma of cervix is transmitted to 0.5 million women each year.<sup>3</sup> “Safe” sex is preached, counseling the use of condoms. These are however, not consistently used by men. The power dynamics of sexual relations and gender inequities prevent women from negotiating with their partners to use a condom. The female condom has yet to have acceptability of both the partners leave aside its cost and limited availability. In this scenario, Women’s Associations, particularly in USA, are urging the development of microbicides with the highest priority, and due to their demand and sustained campaign, NIH has provided generous grants to academia and industry to hasten the development of safe and effective microbicides. About 5 dozen candidate microbicides are in the pipeline. Though some are promising, none has completed all phases of clinical trials successfully against HIV to obtain final regulatory approvals for marketing to the public for protection against HIV and/or other STIs. However, few of these microbicides, passing through clinical safety trials, have the potential of protection against HIV, herpes simplex virus type-2 (HSV-2), gonorrhea, and *Chlamydia trachomatis* transmitted by sexual route. The most promising results are from Center for the AIDS program of research in South Africa (CAPRISA) 004 microbicide randomized trial, which showed effectiveness of topically applied Tenofovir Gel in prevention of HIV and HSV-2.<sup>4</sup> There were no serious adverse reactions. This has the potential to fill the gap in HIV prevention, especially for women who cannot negotiate other methods, such as condom use.

This chapter will summarize the information on the promising candidate microbicides and the rationale on which these are based.

### Definition

Microbicide literally means a product that kills microbes. When marketed for vaginal or rectal use, it should have the ability to kill a variety of pathogens that invade the vagina or rectum by sexual route. Microbicides are inserted by women and therefore only require passive acquiescence of men. Microbicides could be used alone, or in combination with a physical barrier such as condom, diaphragm, to provide increased protection or backup in case of barrier failure. Vaginal use products are usually in the form of creams/gels, pessaries, tablets, films, and sponges.

### Mode of Action of Different Microbicides

Microbicides exercise their action by a variety of ways:

1. by surfactant action dispersing on the membranes;
2. by creating and buffering the vaginal milieu to acidic pH nonconductive to survival and multiplication of pathogens;
3. by blocking the attachment and entry of a virus such as HIV into a host cell;
4. by preventing the integration of the virus;
5. by inactivation via a specific antibody;
6. by inhibiting replication of the virus/infecting microorganisms.

Some microbicides kill the invading microorganisms by yet to be elucidated mechanisms, others may act by multiple mechanisms.

### SURFACTANTS

A number of spermicides are available in the market enabling women to protect themselves against an unwanted pregnancy. A well-known product is Nonoxynol-9 (marketed as, “Today” by Johnson and Johnson). Nonoxynol-9 was also observed to exercise virucidal action on HIV. Hence, one of the first spermicides clinically tested for protection against HIV was a sponge based

N-9 formulation on which clinical trials were conducted. The trial gave the unexpected results of enhancing the transmission of HIV.<sup>5</sup> This was ascribed to inflammation and mucosal damage that N-9 caused to the vaginal epithelium.<sup>6</sup> Industry then tried to improve the characteristics of N-9 based vaginal use products. Excipients were included to cover the mucosal lining and confer bioadhesive properties. Also the release rate of N-9 was regulated to keep its concentration low in the vicinity of the vaginal epithelium. A gel containing N-9, made by a New York based company, with improved characteristics, which was considered safe IN phase-I clinical trials was taken up by UNAIDS initiative for multi centre phase III trials. The results of these trials were disappointing. The product failed to prevent the transmission of HIV by the sexual route.<sup>7</sup> Thus, N-9 based products, though numerous in the market, are unlikely to serve as safe microbicides against HIV.

### Protect Aid Sponge

Alexandre Psychoyos in Paris invented a sponge of polyurethane foam that was impregnated with a gel containing a combination of N-9, benzalkonium chloride (BZK) and sodium cholate, the bile salt.<sup>8</sup> Each surfactant was used at 25 mg/5 g of the gel. The N-9 content was thus 40 times lower than in “*Today*” sponge and BZK was 2.5 times less than in the pharmatex sponge. By decreasing the concentration of N-9 and BZK, it was hoped that the genital irritation effects of these 2 compounds will be substantially, if not completely removed. A third compound, of natural provenance, the bile salt sodium cholate was included so as not to diminish the spermicidal cum antibacterial action. The sponge conferred 100% protection against pregnancy in 20 young women over 1 year of use. Their sexual frequency was at an average 3 times a week. The gel used in the sponge was observed to have anti-HIV effect on the virus *in vitro*. No *in vivo* studies on prevention of HIV or other STIs have been reported.

### C31 G

It is an equimolar mixture of 2 synthetic amphoteric surface active compounds, which have broad-spectrum antimicrobial and spermicidal activity properties.<sup>9,10</sup> Its active agents are alkyl dimethyl glycine (coco betaine) and alkyl dimethyl amine oxide (cocoamine oxide), buffered with citric acid. The alkyl chain length of C12 to C16 resembles the fatty acids of coconut oil. Biosyn company has made a gel (SAVVY®) and a pessary containing C31 G, which are being projected as microbicides. The product acceptability of C31G, when tested for 1 week duration in women was found to be limited due to burning and heat sensation.<sup>11</sup> Trial conducted in 1562 women on SAVVY reported 3.6% higher reproductive adverse events as compared to placebo.<sup>12</sup> Another phase III double blind, randomized, placebo controlled trial in Nigeria has given disappointing results on SAVVY as it failed to reduce the incidence of HIV infection.<sup>13</sup>

### Sodium Lauryl Sulfate

It is another surfactant which was formulated as invisible condom by Universite Laval, Quebec, Canada. It can disrupt both enveloped as well as nonenveloped viruses.<sup>14</sup> It covers the vaginal wall as liquid at room temperature and then transforms into a gel at body temperature, thereby blocking transmission of HIV and other STIs.<sup>15</sup> It has been found safe in rabbit model and two phase-I clinical trials.<sup>16,17</sup> Results of phase II study in 200 cameroon women are pending.

### ACIDIC BUFFERS

The healthy vagina usually has a pH <4.5 due to the presence of lactobacilli in dominant numbers. This pH discourages the growth of many pathogens in the vaginal milieu. It may however, be pointed out that following intercourse, semen neutralizes the acidic milieu enabling the sperms to survive and reach the cervix. This window of neutral pH lasts usually for 2 hours before lactobacilli can make enough lactic acid to bring back the pH to 4. During this period, pathogens transmitted by the male partner can invade the target cells and get established. Keeping these dynamics in mind, a company in Baltimore, USA has patented a gel “BufferGel” made from a polymer, i.e., Carbopol 974P which buffers the pH to about 4. The composition of the gel is such that it can counteract the pH neutralizing effect of semen and thus maintain the pH in acidic range, which is noxious to both the sperms and many pathogens causing STIs. When tested in different animals for prevention of STIs and pregnancy, it showed 87% contraceptive efficacy in rabbits, and significant protection against vaginal and rectal transmission of HSV-2 and *Chlamydia trachomatis*. However, it did not protect against vaginal transmission of *Neisseria gonorrhoeae* in the mouse.<sup>18</sup> The use of BufferGel once or twice daily for 14 days caused no clinically significant change in number of probiotic lactobacilli resident in vagina.<sup>19</sup> This gel has gone through preclinical toxicology and also phase I clinical trials for safety and acceptability. BufferGel application twice daily for 14 days caused a decrease in the prevalence of BV from 30% at enrolment to 6% at 1 week and 7% at 2 weeks.<sup>20</sup> Daily application of BufferGel directly to the penis was found safe and well-tolerated by healthy low-risk and HIV-positive men.<sup>21</sup> Phase II/IIB multicenter trial was undertaken to determine the safety and effectiveness of BufferGel in preventing HIV transmission to women during sex. The results indicate that although the microbicide was safe, it did not have any protective effect against HIV or other STI pathogens.<sup>22</sup>

Another formulation under test, i.e., ACIDFORM which consists of gelling agents, buffer salts, humectants, preservatives, and water in a proprietary mixture. All ingredients are generally regarded as safe (GRAS) except for one, which is currently used in marketed vaginal formulations.<sup>23</sup> The gel caused no vaginal irritation or patient complaints when applied for 6 consecutive days.<sup>24</sup> Its antimicrobial efficacy against herpes and chlamydia

has been established in animal studies.<sup>25</sup> ACIDFORM when used with diaphragm daily for 14 days, appeared to be safe and acceptable in 69 low-risk abstinent women.<sup>26</sup> In a randomized, double-masked, single-center phase I study in circumcised and uncircumcised men to assess penile irritation, safety, and acceptability, use of ACIDFORM for 7 consecutive days gel compared with K-Y® Jelly, was found to be equally safe and well-tolerated by healthy low-risk men.<sup>27</sup> The effectiveness of ACIDFORM as compared with metronidazole gel was found to be significantly less in a double-blind clinical trial for the treatment of symptomatic bacterial vaginosis.<sup>28</sup>

In certain societies, naturally occurring acidic compounds such as lime juice have been used with limited benefit. Recent clinical trials evaluating lime juice have not found it free from toxicity.<sup>29</sup>

## VAGINAL MILIEU PROTECTORS

### Probiotics

Lactobacilli survive and colonise in various cavities and contribute as living sentinels to ward off infections. They secrete lactic acid which is responsible for keeping the pH of healthy vagina around 5. Acidic pH discourages the growth of several pathogens.<sup>30</sup> Several strains but not all, of lactobacilli also secrete around them H<sub>2</sub>O<sub>2</sub>, acting as local antiseptic.<sup>31</sup> Also secreted are peptides (bacteriocins) with antimicrobial properties. By virtue of their colonization, lactobacilli are believed to offer competitive exclusion for attachment of various pathogens.<sup>32</sup> It is obvious that lactobacilli act as local natural “microbicide” offering first line of defense against intruding pathogens. Lactobacillus colonization has been shown to correlate with decreased HIV proliferation.<sup>33,34</sup> Bioengineered lactobacilli (or “live microbicides”) are also being developed to express proteins that bind to HIV and block either viral–host cell fusion or viral entry into host cells. Three proteins expressed through this type of system are functional two-domain CD4,<sup>35</sup> a derivative of gp41,<sup>36</sup> and cyanovirin.<sup>37</sup> These live genetically engineered microbicides are all in preclinical development.

It follows that a good microbicide for vaginal use should be compatible with probiotic lactobacilli resident in the vagina. Not all microbicides developed or in process of developing have been tested for coexistence with lactobacilli.

The species of lactobacilli present in healthy human vagina have been identified in various countries. Vasquez et al.<sup>38</sup> reported the presence of *L. crispatus* in 47.8%, *L. gasseri* in 30.4%, and *L. jensenii* in 17.4% of 23 Swedish women examined. Vallor et al.<sup>39</sup> reported the predominant species as *L. jensenii* (41%) and *L. crispatus* (38%) in USA. Burton et al.<sup>40</sup> from Canada reported that out of 14 subjects harboring lactobacilli, *L. iners* was present in 8/14 (57.1%) and *L. crispatus* in 7/14 (50%) of women; these two species coexisted in 2 subjects. The above mentioned species of lactobacilli were relatively rare in their occurrence in India. The more frequent lactobacilli were *L. reuteri*, *L. fermentum*,

*L. salivarius*, and *L. plantarum* which together were present in 80% of Indian women.<sup>41</sup>

Though lactobacilli are predominant in healthy vagina, they are depleted/absent in women suffering from recurring episodes of bacterial vaginosis (BV) with vaginal pH  $\geq 5$ . In a study done in India, no cultivable lactobacilli could be isolated from 60% of the women. However, the remaining 40% harbored one or more strains of lactobacilli. This anomaly is explainable on the grounds that all strains of lactobacilli do not make high amounts of lactic acid. While both D and L-isomers of lactic acid are secreted by probiotic lactobacilli, it is primarily the D-lactic acid which contributes to low vaginal pH due to its inability to get further catabolized in human energy metabolic pathways.<sup>42</sup> It was found that the mean quantity of D-lactic acid produced by strains from vagina of women with BV is nearly half of the D-lactic acid secreted by the strains of the same species isolated from women with healthy vagina with vaginal pH  $\sim 4$ .<sup>43</sup> This property should be considered in selecting suitable probiotic strains of lactobacilli for replenishment of vaginal flora.

## INHIBITORS OF HIV ENTRY

### Polyanionic Compounds

#### PRO 2000

PRO 2000 (Indevus Pharmaceuticals, USA) is a synthetic, long-chain, naphthalene sulfonic acid polymer consisting of alternating 2-naphthalene sulfonic acid sodium salt and methylene units, a synthetic carbomer gelling agent, pH 4.5 buffer, and a combination of preservatives. These interfere with the virus adsorption process by disrupting the initial binding and membrane fusion steps of HIV-1 infection.<sup>44</sup> It binds to CD4 with nanomolar affinity and blocks binding of HIV gp120 to CD4. It inhibits infection by a wide range of HIV isolates in a variety of cell types. Phase I clinical trials in Europe,<sup>45</sup> the USA, and South Africa<sup>46</sup> showed that PRO 2000 was generally well-tolerated; however, at the highest concentrations tested (4%), it was associated with a slightly higher incidence of intermenstrual bleeding compared with placebo.<sup>47</sup> Clinical investigations are continuing with PRO 2000/5 alone (phase III) and a combination of PRO 2000/5 and BufferGel (phase II/IIB safety and efficacy study) for preventing vaginally acquired HIV infection.<sup>48</sup>

#### Cellulose Sulfate

Cellulose sulfate (Ushercell, Polydex Pharmaceuticals, Canada and Topical Prevention of Conception and Disease [TOPCAD], USA): Cellulose sulfate acts by binding with the V3 loop of the gp120 HIV-1 envelope, and it can inhibit both CXCR4 and CCR5-tropic virus for attachment.<sup>49</sup> It has contraceptive property<sup>50</sup> and in preclinical studies, it showed activity against HIV, HSV-1 and 2, HPV, *N. gonorrhoeae*, *Chlamydia trachomatis*, and *G. vaginalis* and no noxious activity

against lactobacilli.<sup>51–53</sup> Phase I safety studies on cellulose sulfate, which involved 518 women and 48 men, found the gel to be safe.<sup>54</sup> Two phase III efficacy trials of cellulose sulfate versus placebo were initiated in Africa and India, but both studies were halted in 2007 after interim analysis of one of the studies showed a higher HIV seroincidence than expected in the cellulose sulfate arm. Of 1425 women enrolled (717 in the cellulose sulfate arm and 708 in the placebo arm), there were 25 seroconversions in the cellulose sulfate arm compared with 16 seroconversions in the placebo arm.<sup>55</sup> The second phase III study was halted as a precaution because of safety concerns arising from the first trial.<sup>56</sup>

A number of other sulfated polymers have been tested. Sulfonated polystyrene, besides the expected antiviral invasion properties, agglutinates sperms and inhibits acrosin, blocking fertilization. Zanveld et al. have made formulations containing polysulfated styrene and cellulose for similar purposes.<sup>57</sup>

### Carraguard

Carraguard (Population Council, USA): David Philips at population Council Labs, New York was the first to point out that carragenins extracted from sea weed prevents the attachment of HIV from leukocytes to epithelial cells.<sup>58</sup> The extract is not only cheap but safe and is used in chewing gum with no observed toxicity. The test product named “Carraguard” is a gel formulation of a mixture of  $\lambda$  and  $\kappa$ -carrageenans derived from red seaweed.<sup>59</sup> It has gone through phase I and II extended safety trials where it was found to be safe and acceptable.<sup>60,61</sup> However, the phase III trial conducted to test the efficacy of Carraguard for prevention of HIV infection in women in South Africa did not show significant protection.<sup>62</sup>

### Cellulose Acetate Phthalate (CAP)

CAP blocks gp120 binding sites on HIV and also blocks CXCR4 and CCR5-tropic virus types in tissue explants and animal models.<sup>63,64</sup> It has shown *in vitro* activity against HIV-1, HSV-1, and HSV-2.<sup>65</sup> It is being developed as both a film and micronized gel. The micronized form has the advantage of providing acidic environment which causes disintegration and loss of infectivity of HIV-1.<sup>66</sup> Phase I trial of 13% gel was halted because of heavy vaginal discharge in all participants, attributed to the hyperosmolarity of glycerol based formulation.<sup>67</sup>

### Dendrimers

They are new anionic macromolecules containing a central core, interior branches and terminal surface groups adapted to specific targets; thereby binding to multiple locations on multiple cells. The first dendrimer tested clinically was SPL 7013 (Vivagel, Starpharma Holdings Ltd. Melbourne, Australia). It provided protection from simian/human immunodeficiency virus (SHIV) in macaque model and from HSV-2 in animal models.<sup>68,69</sup> It has

been well-tolerated in phase I safety trial in Australia on males<sup>70</sup> and another phase I trial in Kenya and USA is in progress.

### CCR5 Blockers

Another mechanism of preventing entry of HIV is by inhibiting CCR5; an important coreceptor for macrophage-tropic viral strains. One such inhibitor is PSC-RANTES, which exhibits *in vitro* antiviral activity against all strains of HIV and inhibits HIV-1 infection of Langerhans cells, crucial cells for HIV-1 transmission across the vaginal epithelium.<sup>71</sup> It protected macaques from SHIV SF 162 without any systemic toxicity/absorption.<sup>72</sup>

Another such antagonist is CMPD 167, a cyclopentane based compound formulated as 5 mmol vaginal gel. It provided protection from vaginal SHIV in eight of ten macaques.<sup>73</sup>

The drawback of using CCR5 blockers is their inability to block the entry of CXCR4-tropic virus. Though this pathway is less important in sexual transmission, prolonged use of CCR5 inhibitors may put pressure on HIV-1 to shift toward the use of non-CCR5 pathways/coreceptors to gain entry into host cells. An effective microbicide should block all modes of receptor mediated entry of HIV.

## ANTIMICROBIAL COMPOUNDS

### Magainins

These are a group of cationic peptides, 21 to 27 residues in length, isolated from the skin of African clawed frog (*Xenopus laevis*) and have antibacterial, antifungal, antiprotozoan, antiviral, and antispermatozoal action.<sup>74</sup> At low concentrations they inhibit the growth of numerous species of bacteria and fungi and induce osmotic lysis of protozoa. The peptides assume an amphibilic alpha helix structure in a hydrophobic environment and punch holes in the cell walls of infecting organisms.<sup>75</sup> Laboratory evaluation of magainin-A revealed that the peptide inhibits the growth of STIs but not HIV-1 and HIV-2.<sup>76</sup>

### Nisin

It is a cationic peptide of 34 amino acids and molecular mass of 3.5 kDa produced by the bacterium *Lactococcus lactis*. For the last 50 years, Nisin has been used as a food preservative throughout the world; hence, the WHO and the US Food and Drug Administration (FDA) have conferred GRAS (generally regarded as safe) status on the peptide.<sup>77</sup> Safety and contraceptive efficacy of Nisin was evaluated in rats, rabbits, and monkeys, and it was proposed that Nisin could serve as a safe vaginal contraceptive.<sup>78,79</sup> Repeated application of high dose of Nisin gel (15,150 microM/day for 14 days) on cervicovaginal epithelium of rabbits caused no abnormality in structural integrity of vaginal epithelium and no change was noticed in the cytokines from cervicovaginal lavage (CVL).<sup>80</sup>

## Novispirin G-10

A novel antimicrobial alpha-helical octadecapeptide structurally related to cathelicidins and other innate immunity peptides is reported to be useful to prevent chlamydial infection and/or rectify the abnormal vaginal flora associated with BV.<sup>81</sup>

## Defensins

These are peptides secreted by mammalian cells with unusually broad spectrum of action on gram-positive and gram-negative bacteria, many fungi, mycobacteria, spirochetes, and several enveloped viruses. They are amphipathic peptides with complex folding, rich in antiparallel beta-sheet and devoid of alpha-helical domains.<sup>82</sup>

## Docosanol

Also known as behenyl alcohol, docosanol is a 22 carbon saturated alcohol mainly used as an antiviral agent, specifically against HSV.<sup>83</sup> It inhibits viral replication by interfering with fusion or early intracellular events following viral entry into target cells.<sup>84</sup>

## Squalamine

It is an aminosterol isolated initially from the shark, but has since been chemically synthesized. It exhibits potent bactericidal activity against both gram-positive and gram-negative bacteria. It is fungicidal and also causes lysis of protozoa.<sup>85</sup>

## HUMANIZED MONOCLONAL ANTIBODIES

Antibodies of high affinity have exquisite capability of specifically recognizing a ligand or epitope present on microbes or sperms. In case antibodies are developed to critically important epitopes, they can inactivate and block the sperm function, and/or prevent infection by a given pathogen. Antibodies constitute a natural arm of the body's defence system. Hybridomas secreting monoclonal antibodies can easily be generated in mice. The mouse monoclonals are valuable reagents for diagnostics but cannot be used for therapeutic purposes due to sensitization of humans to mouse proteins. This barrier has been broken with the development of technologies enabling humanization of mouse monoclonals. A number of chimeric antibodies have received FDA authorization for therapy of chronic diseases and cancers. The high cost of humanized recombinant antibodies can be reduced substantially by their expression in plants.

Kevin Whaley at Johns Hopkins University has pioneered in assessing the utility of antibodies for use locally in vagina to control fertility and prevent transmission of pathogens. Data reported so far is of work done in experimental animals. They have also developed a controlled delivery system for long term release of antibodies for passive immunoprotection.<sup>86,87</sup> This is an

attractive approach as it simulates a physiological mechanism. It will however, be difficult to develop effective antibodies against the large number of microorganisms that invade the vagina.

## HIV REPLICATION INHIBITORS

Current microbicide research is focused on the identification and development of novel nondetergent spermicidal nucleoside and non-nucleoside inhibitors, aimed at preventing sexual transmission of HIV. A preclinical evaluation of TMC120 (4-[[4-[(2,4,6-trimethylphenyl)amino]pyrimidin-2-yl]amino]benzenecarbonitrile), a diarylpyrimidine, that was the first non nucleoside reverse transcriptase inhibitor (NNRTI), has shown it to have *in vivo* effectiveness as a topical microbicide in preventing HIV-I transmission in a humanized severe combined immunodeficient (hu-SCID) mouse model.<sup>88</sup> It is now being tested in several phase I and II trials. One formulation employs a slow release vaginal ring, which would allow for once a month, non-coitally dependent dosing.

## Tenofovir

Tenofovir disoproxil fumarate (TDF), a reverse transcriptase inhibitor, marketed by Gilead Sciences under the trade name Viread, was approved by the USFDA on October 26, 2001 for the treatment of HIV, and on August 11, 2008 for the treatment of chronic hepatitis B. A 2006 trial by the Family Health International, employed orally either tenofovir or placebo in 936 high-risk women in Cameroon, Ghana, and Nigeria. Overall, a total of eight HIV infections occurred in women in the study, including those randomized to receive Tenofovir or placebo. These infections were too few than initially estimated in the design of the study. Thus, data was insufficient to determine Tenofovir's effectiveness against HIV infection. Additional studies with more participants were required to determine efficacy.<sup>89</sup>

A topical gel form of Tenofovir (1%) was developed to prevent the sexual transmission of HIV. A phase IIb trial of 1% Tenofovir gel in South Africa sponsored by the Centre for the AIDS Programme of Research in South Africa (CAPRISA) on 980 women has been recently completed. HIV incidence in the Tenofovir gel arm was 5.6 per 100 women-years (person time of study observation) (38 out of 680.6 women-years) compared with 9.1 per 100 women-years (60 out of 660.7 women-years) in the placebo gel arm (incidence rate ratio = 0.61;  $p = 0.017$ ). In high adherers (gel adherence >80%), HIV incidence was 54% lower ( $p = 0.025$ ) in the Tenofovir gel arm. In intermediate adherers (gel adherence 50–80%) and low adherers (gel adherence <50%), the HIV incidence reduction was 38% and 28%, respectively. Tenofovir gel reduced HIV acquisition by an estimated 39% overall, and by 54% in women with high gel adherence. No increase in the overall adverse event rates was observed. There were no changes in viral load and no Tenofovir resistance in HIV seroconverters.<sup>90</sup>

Another efficacy trial is intended to compare oral pre-exposure prophylaxis with Tenofovir and a combination of Tenofovir plus emtricitabine, with topical use of Tenofovir gel.

## Serine Proteinases and Their Inhibitors

Inhibitors of serine proteinases are observed to inhibit replication of HIV without cytotoxicity.<sup>91</sup> The compound TLCK acts on both cell contained and cell-free virus. It also blocks fertilization presumably by inhibiting acrosin. Another synthetic inhibitor AGB (4-acetamido phenyl 4-guanidinobenzoate) has more potent contraceptive properties than the benchmark N-9 and has also a strong anti-HIV action.<sup>92</sup>

## COMBINATION MICROBICIDES BASED ON MULTIPLE MECHANISMS OF ACTION

### Polyherbal Microbicides

The ingredients employed are from plants which have been used for centuries by humans without any serious side effects. More than one active ingredient is employed in the formulation to act at different points, ideally aimed to prevent/cure a wide spectrum of RTIs and STIs.

#### Praneem Polyherbal Tablet (PPT)

It is a formulation composed of purified quality controlled extracts of Neem (*Azadirachta indica*) leaves, saponins from *Sapindus mukorossi*, quinine hydrochloride and *Mentha citrata* oil dispensed with excipients maintaining pH of the formulation at 4.<sup>93</sup> Leaves, bark, and kernel of Neem tree contain about 100 tri, tetra, and penta terpenoids, 25 of these are characterized chemically. They exercise a wide spectrum of action on fungi,<sup>94</sup> bacteria,<sup>95</sup> and viruses.<sup>96</sup> Neem extract stimulates immune responses particularly of Th1 type.<sup>96,97</sup> Saponins contribute to spermicidal and contraceptive property. Each component of the PPT has spermicidal properties, their combination is, however, synergistic and enhances the spermicidal activity by 8-folds.<sup>98</sup> Spermicidal action on human sperm is not only evident *in vitro* but also *in vivo*, as demonstrated by post coital tests.<sup>99</sup> In addition to killing of sperms, the migration of sperm to cervical mucous is inhibited by PPT to a better extent than by the N-9 containing pessary, "Today".<sup>100</sup>

PPT inhibits the growth of normal and penicillin resistant strains of *N. gonorrhoeae*. It also inhibits urinary tract *E. coli* (including multidrug-resistant [MDR] strains), *Candida tropicalis*, and *Candida krusei*.<sup>93</sup> PPT prevents the transmission by vaginal route of Herpes simplex virus type 2 and *Chlamydia trachomatis* in progestin sensitized mice as determined by researchers at Johns Hopkins University. Praneem was also found to exercise virucidal action against HIV-1 by the discoverer of the virus Nobel Laureate Françoise Barre Sinoussi and Annie David at the Institut Pasteur, Paris.<sup>93</sup> Phase I safety trials on PPT were conducted in 3 institutions in India. Seven consecutive days use caused

no damage to vaginal epithelium or had any effect on cervical cytology and metabolic and organ functions of recipients.<sup>101</sup> Extended Phase I/II safety study was carried out on PPT at the National AIDS Research Institute (NARI), Pune on a cohort of monogamous married women and professional sex workers. Fourteen consecutive day use of the tablet was well-tolerated, with no significant abnormality observed on colonoscopy.<sup>102</sup> The pre-coital acceptability of PPT by both partners was reported to be high.<sup>103</sup>

Praneem prevents the integration of HPV-16 in infected cervical cells. Twenty women molecularly diagnosed positive for HPV16 infection with or without low-grade squamous intraepithelial lesion (LSIL) were assigned to receive intravaginal, topical application of either Praneem tablet or placebo for 30 days excluding the days of menstrual period and were evaluated for persistence of HPV infection using HPV L1 consensus and HPV type 16-specific PCR. One course of Praneem resulted in elimination of HPV in 6 out of 10 (60%) cases. A repeat course in four patients with persisting HPV infection caused clearance of HPV in two additional cases resulting in an overall clearance in 80% as against a spontaneous clearance of 10% (1/10) seen in the placebo arm. The elimination of HPV DNA was found to be accompanied by marked improvement in cytological abnormalities of Praneem-treated patients.<sup>104</sup>

## BASANT

It is another polyherbal formulation developed by the workers at Talwar Research Foundation. It contains 95% pure diferuloyl methane (curcumin), purified extracts of Amla (*Emblica officinalis*), Neem leaf extracts, purified saponins from *Sapindus mukorossi*, purified Aloe vera powder and rose extract water. Curcumin has anti-inflammatory<sup>105</sup> and anticancerous properties.<sup>106</sup> It blocks the cancer pathway by downregulating the NF- $\kappa$ B activation<sup>107</sup> by suppression of I $\kappa$ Ba kinase and Akt activation.<sup>108</sup> These attributes are desirable in a microbicide to be applied in the vagina and cervix. Curcumin is safe and its intake at as high as 8 g every day for 3 months by humans causes no ill effects.<sup>109</sup> Curcumin also inhibits HIV-1 LTR directed gene expression and virus replication.<sup>110</sup> It inhibits HIV-1 and HIV-2 proteases<sup>111</sup> and also has inhibitory activity against HIV-integrase<sup>112</sup> thus preventing the viral DNA to become a part of the host cell. Barthelemy et al. showed that curcumin used at 10–100 nm concentration inhibited tat transactivation of HIV-1–LTR lacZ by 70–80% in HeLa cells.<sup>113</sup> Curcumin also inhibits UV-light induced HIV gene expression.<sup>114</sup> Curcumin selectively down regulates HPV 18 transcription as well as AP-1 pathway in HeLa cells. It also causes reversal of c-fos/fra-1 transcription to normal state in tumorigenic HeLa cells and can thus control transcription of pathogenic HPVs during keratinocyte differentiation and progression of cervical cancers.<sup>115</sup>

Antioxidant properties of amla are less due to ascorbic acid and more due to the polyphenols such as ellagic acid, gallic acid, and tannins.<sup>116</sup> El Mekawy et al. reported that the methanolic extract of the Amla fruit has an inhibitory effect on HIV-1 reverse transcriptase.<sup>117</sup>

Aloe vera has a soothing effect on mucosal linings and is reported to have wound-healing properties.<sup>118</sup> Fahim and Wang reported that 7.5% and 10% lyophilized Aloe was toxic to sperm tail causing immobilization of spermatozoa but produced no irritation or ulceration of rabbit vaginal epithelium.<sup>119</sup> It has a considerable inhibitory effect on HIV and HPV.<sup>120</sup>

Rose water extracted from rose petals has a pleasant fragrance and is used in perfumery preparations.

BASANT inhibits standard strains and clinical isolates of *N. gonorrhoeae* including those resistant to penicillin, tetracycline, ciprofloxacin, and nalidixic acid.<sup>120</sup> It also acts against *Candida albicans*, *Candida glabrata*, *Candida krusei*, *Candida tropicalis* including strains resistant to fluconazole, Itraconazole and amphotericin B. It prevents entry of HIV-1 in P4-CCR5 cells and inhibits the replication of NL4.3 HIV in CEM-GFP and P4 cells, EC<sub>50</sub> = 1:20,000 dilution.<sup>120</sup> It also inhibits transduction of HPV 16 in Hela cells.<sup>120</sup> BASANT inhibits *Chlamydia trachomatis* both pre and post infection.<sup>121</sup>

BASANT was found nontoxic to human vaginal tissue and did not induce inflammatory cytokines. It effectively inhibited the entry and replication of both T-tropic and macrophage-tropic HIV-1.<sup>122</sup>

BASANT is currently in phase II clinical trial at Chitranjan National Cancer Centre, Kolkata in women with cervical dysplasia molecularly positive for HPV 16/18 with the idea of determining whether 30 applications of BASANT can eliminate HPV and regress early cancerous changes.

Another Phase IIb trial is in progress at the All India Institute of Medical Sciences and Sir Gangaram Hospital New Delhi in women with recurring episodes of Vaginitis/vaginitis, with vaginal pH >5. The prevailing infection is treated with BASANT followed by administration of probiotics. A combination of BASANT with three strains of Lactobacilli (*Lactobacillus fermentum* TRF#36, *Lactobacillus gasseri* TRF#8, and *L. salivarius* TRF#30) was found to be highly beneficial in these women. Seven to 14 days intake of BASANT plus probiotics intravaginally cured the prevalent infections and prevented their recurrence. It also restored the pH of vagina to normal acidic range. The cited strains of probiotics were selected on the merit of their high capacity for production of D-Lactic acid, their colonization potential in the vagina, their ability to secrete hydrogen peroxide around them, and their possession of Arginine deaminase preventing the production of foul odor. All strains were initially isolated from eco healthy vagina.

Microbicides discussed above have largely been tested in women for their ability to prevent transmission by heterosexual vaginal route. Intercourse by rectal route is more vulnerable. The rectal mucosa consists of one layer of columnar epithelium, and the subepithelial lamina propria contains many cell types to which HIV binds. Rectal lymphoid follicles contain M cells, which bind and present HIV-1 to underlying lymphoid tissue.<sup>123</sup>

Circumcision lowers significantly (50–76%) the transmission of HIV from infected women to their male partners, as observed in more than one trial in Africa.<sup>124–126</sup> This is understandable on the grounds that foreskin of the penis harbors macrophages expressing CD4 receptors and dendritic cells carrying intercellular adhesion DC-SIGN molecules.<sup>127</sup>

## Conclusion

Many of the formulations were primarily tested for preventing HIV transmission. Four microbicides namely, COL-1492, Carraguard, cellulose sulfate, SAVVY which did reach the phase III stage were not able to provide any significant protection against HIV. Some, contrary to expectations, even enhanced HIV transmission owing to the damage that they caused to the mucosal lining and vaginal epithelium. At present, ongoing phase III/IIB trials against HIV are on (i) Pro 2000/5, (ii) Pro 2000/5 in combination with BufferGel, (iii) Tenofovir gel (1%), and (iv) Tenofovir in combination with emtricitabine. The emerging trend is to use combinations rather than single active compounds. Intervention at more than one point is likely to result in better efficacy. Furthermore safety tested on a limited number of subjects as per standard format of phase II may not be sufficient to guarantee the safety on a larger number of subjects or with use of the product for a longer period. Better clinical trials protocols are being drawn in light of the past experience.

HIV is in fact not the only infection transmitted sexually. Infections due to *N. gonorrhoea*, Chlamydia, HSV, and HPV are transmitted in much larger numbers. It is in this context that efforts are also being directed to develop microbicides preventing reproductive tract infections and other STIs. This chapter summarizes the variety of compounds and formulations being developed. Those currently under clinical trials, after thorough preclinical studies are described in Table 13.1.

Attention has been drawn to the innate defense accorded by resident probiotic lactobacilli in vagina. A conjoint use of microbicide and probiotics is recommended for reproductive health and prevention of STIs.

**Table 13.1:** Microbicides of Interest Currently Under Clinical Trials

Active principle (Name)	Developed by	Mode of action	Status
Sodium lauryl sulfate (invisible condom)	Universite Laval, Canada	Surfactant, spermicidal, nonspecific disruption of enveloped and non-enveloped viruses	Phase II/III efficacy trials for protection against HIV
ACIDFORM (Amphora)	Instead Inc, USA	Spermicidal, acidifying agent	Phase III trials in progress with diaphragm for prevention of <i>N. gonorrhoeae</i> and <i>C. trachomatis</i>
Carbopol 974P (BufferGel)	ReProtect, USA	Spermicidal, acidifying agent	Phase II/IIb trials against HIV in progress
Naphthalene sulfonate (PRO 2000)	Indevus Pharmaceuticals, USA	Anionic polymer Negative charge interferes with attachment of HIV to CD4+ cells	Phase III for prevention of HIV in women
(PRO 2000/5 + BufferGel)	Indevus Pharmaceuticals + ReProtect, USA	Polyanionic + acidic buffer	Phase IIB safety and efficacy trials against HIV in progress
Dendrimers: SPL 7013 (Vivagel)	Starpharma, Melbourne	Entry inhibitor, protects against SHIV and HSV-2 in monkeys	Found safe in phase I studies in Australia; phase I in USA and Kenya planned
Tenofovir (Viread)		Nucleotide analogue; Reverse transcriptase HIV replication inhibitor	Two Phase IIB trials in progress: (i) 1% Tenofovir gel; (ii) oral Tenofovir + Emtricitabine vs. 1% Tenofovir gel
Diarylpyrimidine (TMC 120)		Non-nucleoside analogue; Reverse transcriptase inhibitor	Phase I/II trials in progress
Thiocarboxanilide (UC 781)		Non-nucleoside analogue; Reverse transcriptase inhibitor	Phase I trial in progress
Praneem Polyherbal tablet (PPT)	Talwar Research Foundation, Panacea Biotec	Multiple mechanisms; Prevents HIV replication and HPV integration	Phase II study for elimination of HPV-16/18
BASANT	Talwar Research Foundation	Multiple mechanisms; prevents entry, replication, and integration of T-tropic and M-tropic HIV; inhibits entry of HPV	Phase IIB trials for elimination of HPV-16/18
BASANT + Probiotics	Talwar Research Foundation	Wide-spectrum antimicrobial action of BASANT + restoration of healthy microflora and defense by lactobacilli by virtue of production of H <sub>2</sub> O <sub>2</sub> , lactic acid, and bacteriocines	Phase II/III trials indicate cure of vaginosis/vaginitis & restoration of vaginal pH to acidic range

# Information and Communication Technologies to Support HIV and STI Care in Developing Countries

Walter H. Curioso • Magaly Blas • Antonio Bernabe-Ortiz  
• Freddy Canchihuaman • Patricia J. Garcia

# 14

## Introduction

The Internet, personal digital assistants (PDAs), cell phones, and other innovative technologies are part of a growing arsenal in the global effort to prevent and control HIV and other sexually transmitted infections (STIs). Appropriately utilized technologies may improve HIV/STI screening, prevention, surveillance, and care for patients and populations. In this chapter, we review the published literature regarding the use of information and communication technologies (ICT) to support HIV and STI with a particular focus in developing countries.

We will start by describing the two applications that we consider have the most potential to support HIV and STI care in developing countries: mobile devices and the Internet. Then we will describe some notable examples of information systems used for clinical care in developing countries. Finally, we will present how ICT are supporting education and professional development for healthcare workers treating HIV/STIs in developing countries.

## Mobile Health to Support HIV and STI Prevention and Care

Mobile health (medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, PDAs, and other wireless devices) has tremendous potential to support HIV and STI care and is currently demonstrating its impact. In particular, the use of short text messaging (SMS) provides many options for public health interventions.<sup>1</sup> For example, text messaging can be used for:

- Sending information to patients
- Gathering information from health personnel and patients
- Getting answers to questions
- Connecting people to people
- Performing transactions

### SENDING INFORMATION TO PATIENTS

This is the simplest way to use SMS.<sup>2</sup> Patients could receive messages from an institution such as a healthcare organization,

clinic, hospital, university, etc. Patients do not need to respond necessarily to the messages. They can just read the text they receive. Three specific applications are described below:

### Educating Patients

Cell phone text messaging can be used for educating patients about sexual health. For example, the San Francisco Department of Public Health currently uses SMS to promote sexual health by sending messages about HIV and STI to adolescents.<sup>3</sup> Mobile devices displaying soap opera videos, could be used also to reduce young urban women's HIV sex risk.<sup>4</sup>

### Notifying Patients

In this case, an institution sends messages whenever is needed, not on schedule. These messages may contain urgent information, such as a critical laboratory result. However, the notifications do not need to be urgent. For example, cell phones can be used for partner notification. In Australia, a website allows patients diagnosed with an STI to send an SMS or e-mail to partners who may have been exposed.<sup>5</sup> Regarding provision of test results, SMS sent to patients with *Chlamydia trachomatis* infection in a health clinic resulted in a decreased time to treatment of the infection.<sup>6</sup>

### Reminding Patients

Mobile phones can be used to send reminders. In this case, the person receives a text message on his/her mobile phone without any need to reply. The reminder could be about remembering to take antiretroviral therapy (ART) each morning (with the aim of increasing antiretroviral adherence). For example, Puccio and colleagues developed a program that used cell phone reminders to improve adherence in HIV-infected adolescents and young adults who were either going to begin an ART regimen for the first time or begin a new ART regimen.<sup>7</sup> In a systematic review conducted by Wise and Operario, four out of eight studies showed that patient adherence to ART was significantly improved with the use of electronic reminders as a stand-alone adherence strategy, but data on

the improvement of virological or immunological outcomes were not clear. At the moment, there is not enough evidence to demonstrate the effectiveness of medication reminders in HIV positive patients.<sup>8</sup>

In a simulation model of effective medication adherence improvement strategies, electronic reminders were found to be the least expensive of all adherence strategies, with an approximate monthly expense of \$50.<sup>9</sup> Therefore, more research is needed in order to establish a conclusive statement on the effectiveness of electronic reminders. In the meantime, more promising research is coming from developing countries. For example, in Peru, the Cell-Pos computer-based system uses cell phones and the Internet to enhance adherence to antiretroviral treatment (via SMS reminders) and to support HIV transmission risk-reduction among adults living with HIV/AIDS.<sup>10</sup>

Preliminary research by Curioso from the Cell-Pos project demonstrated that participants were receptive to the idea of receiving reminders via SMS, but specified certain characteristics they wanted the messages to have (such as being simple and concise). It was also important that the messages maintained confidentiality and privacy by using coded words or phrases (e.g., “Remember, it’s time for your life”) instead of “sensitive” words (e.g., HIV or antiretroviral). Patients wanted healthcare SMS that appropriately notified them, delivered a carefully crafted message, and appropriately ensure privacy, security, and confidentiality.<sup>11</sup> Cell phones are being used by the Cell Life project to support patient treatment adherence in South Africa.<sup>12</sup> Similarly, a cell phone system is being used in Rwanda to connect a large percentage of HIV clinics, improving reports of antiretroviral drugs stocks.<sup>13</sup>

Cell phones have also been used to reduce nonattendance to health clinics (through appointment reminders). Dyer and colleagues (2003) found that missed appointments decreased by 8% when SMS reminders were implemented in a London sexual health clinic.<sup>14</sup> A study conducted in Australia with outpatient clinics found that patients reminded of their appointment by SMS were significantly less likely to miss an appointment than a control group.<sup>15</sup> In a study conducted at John Hunter Clinic for Sexual Health in London, Price et al. showed that the use of text appointment reminders to increase utilization of clinic resources was efficient, cost-effective, and acceptable to patients.<sup>16</sup>

Future research on electronic reminders may include the development of software packages designed to support, educate, and remind patients about their treatment regimens. New advances in technological development could transform text reminders into multimedia messages that include realistic images of the medication to be taken (or other preferred images), support messages, and interactive elements.<sup>8</sup>

## GATHERING INFORMATION FROM HEALTH PERSONNEL AND PATIENTS

### Collecting Data from Health Personnel and Patients

This feature could be implemented through interactive voice response (IVR), data entry using key pads, or via SMS. An example

of data collection using ICT is Cell-PREVEN, a pilot project within a large randomized trial of 20 cities called PREVEN, which sought to lower STD rates in Peru.<sup>17</sup> Cell phones were exclusively used to report adverse events to metronidazole treatment among sexual workers. Health workers reported in real time to the system via IVR. If an adverse event was reported, the central system sent e-mail and SMS alerts to the researchers. Donald et al. from the Cell Life project found that cell phones made the recording of data very efficient, saving time, reducing the risk of losing patient notes and reducing potential breaks in confidentiality.<sup>18</sup>

Other mobile devices such as PDAs are frequently used for data collection. For example, Colecta Palm was a pilot project that involved the use of PDAs to enhance adherence to antiretroviral treatment and to support safer sex and HIV transmission risk reduction for people living with HIV/AIDS.<sup>19</sup> The pilot showed that PDAs could be a culturally appropriate way to approach and support people living with HIV and AIDS (PLWHA) in Lima.<sup>19</sup> In addition, low-cost PDAs have been used to collect sensitive sexual behavior data in Peru from young men and women, within the PREVEN study mentioned above, with very high acceptability.<sup>20</sup>

Additional promising open-source platforms could be used to develop data collection tools for mobile devices.<sup>1</sup>

## Journaling by Individuals

People can send SMS to keep a personal journal related to their health behavior. For example, a person can keep track of his/her diet by texting the number of calories consumed or the steps walked each day if the person is monitoring his/her exercise patterns. Diary entries, or active requests, via SMS have worked well in motivated and self-efficacious patients because mobile phones are a part of people’s everyday lives.<sup>21</sup> A mobile phone-based service would allow a health provider instantly to view which clients are creating daily entries.<sup>22</sup> This would act as a screening device, by revealing which patients are motivated and allowing for more time and effort to be spent on the less motivated patients.<sup>22</sup> One of the disadvantages of this feature is that it is mainly designed for individual use, not for large-scale data analysis by health organizations.<sup>2</sup>

## GETTING ANSWERS TO QUESTIONS

### Getting Answers from a Database

People can ask questions related to health using texting. When they get a response, they receive an answer from a database. One of the advantages of this feature is convenience. Sometimes the phrasing of the messages needs to be changed so that users are more likely to continue using the system. Services need to be in touch with the community they serve in order to create services that are spread via social networks and recommendations from friends. SexInfoSE, based in San Francisco, uses social marketing to advertise an SMS-based risk assessment for STI. For example, if your condom broke and you don’t know what to do, you can

text “sexinfo 1” to 61827 in San Francisco, then the service SexInfoSF.org<sup>23</sup> gives you the following information: “U may b at risk 4 STDs + pregnancy S.E.Clinic, Keith at Armstrong St, 415-671-7000 M-F9-5, W8-12, City Clinic 356 7<sup>th</sup> St 415-487-5500 MWF 8-4 TuTh -4.”<sup>23</sup>

Another advantage is privacy (or perception of privacy), because the person can request the information without being noticed. One of the main disadvantages is the 160-character limitation of SMS. This issue could be frustrating because people may not receive enough information or even the correct information. Another potential limitation is that the patient might need to know in advance the phrasing of the question they hope to receive an answer to (or be able to select it from a list of options).

### Getting Answers from a Real Person

People can send a sexual health question using SMS and receive an answer back from a real person (e.g., a doctor or a nurse), not a computer.<sup>2</sup> In this case, a doctor or a nurse may give more appropriate answers than a computer. One of the advantages is that organizations such as hospitals or clinics can set up specific days for this kind of services. One of the considerations is to adequately train health personnel on how to use SMS. Health personnel might even use regular computers connected to the Internet to send and receive the incoming questions. As one of the counselors in the Cell-Life project mentioned<sup>18</sup>: “The cell phones have made a big difference, as it’s easy to reach a client and they can phone me anytime if they have problems.” One of the main disadvantages is the cost involved in the operation of the system by health personnel. In addition, privacy and confidentiality issues need to be carefully addressed.

### CONNECTING PEOPLE TO PEOPLE

Social networks are very popular nowadays. For an effective provision of care for chronic conditions, including HIV, it is necessary to engage the patient and the community which supports him or her.<sup>24</sup> Two specific uses follow below.

#### Connecting Individuals

Physicians and patients can interact via texting. In fact, text messaging is an easy and, many times, a convenient way of allowing patients to keep in touch. Doctors can improve communication with patients using SMS.<sup>25</sup> For example, patients could report adverse events to their doctors using text messages. In addition, peer educators can stay connected with HIV patients and friends can support friends.

#### Connecting Groups

Text messaging supports one-to-one conversations as well as many-to-many discussion.<sup>2</sup> One of the best examples is Twitter, which was launched in 2007. Group support has long been an important strategy in changing health behavior, and now

increasingly SMS facilitates group interactions.<sup>2</sup> In fact, support groups, discussion threads, and collective action are now all possible using regular phones and text messaging.<sup>2</sup> This feature needs to be further explored in future studies.

Project Zumbido in Mexico aims to record the usage patterns and evaluate whether a system using mobile phones with unlimited text messaging helps to increase the level of social support experienced by HIV positive patients of an antiretroviral clinic.<sup>26</sup>

### PERFORMING TRANSACTIONS

#### Getting Things Done

This is an emerging use of texting. In this case, people can set up clinic appointments, register for peer activities at the clinic, or at the gym, etc.<sup>2</sup>

Three key issues related to the use of cell phones for healthcare are health data privacy, security, and confidentiality. Indeed, these issues are applicable to every stage of the use of cell phones for healthcare, including capturing personal health-related data from a cell phone, uploading it to a server, transmitting it to a web-based or other form of electronic personal record or medical record, using the data for interpretation and professional judgments in the care of that individual, and responding back to the person via, for example, an SMS message. Another concern is that while a cell phone might be used predominately by a specific person, it may occasionally be shared or left unlocked in a purse, on the table at home, or on the desk at work.<sup>27</sup>

### Role of the Internet to Support HIV and STI Prevention and Care

The Internet constitutes a potential source of information in healthcare (more than 43% of Internet users have used the Internet to seek health information). Patients can search for information about their diagnosis, seek out healthcare providers, and explore treatment options.<sup>28</sup> However, the Internet can also be used to solicit sexual partners.<sup>29</sup> Men who have sex with men (MSM) is a population that more actively seeks online sexual partners, at a rate approximately 7 times more frequently than non-MSM.<sup>30</sup> Seeking sexual intercourse on the Internet is a risk factor for HIV and STI transmission.<sup>31–33</sup> Individuals who seek sex partners through the Internet may report a higher level of sexual risk behaviors such as higher number of partners, more anal sex, and more sexual exposure to partners known to be HIV positive compared to those who do not use the Internet to find sex partners.<sup>31</sup>

Studies of patients of STI clinics also found that among this core group, the Internet is a common venue for meeting and having sex with partners. In San Francisco, MSM with early syphilis infections reported the Internet as the most common place to meet sex partners, followed by bars, bath-houses, and sex clubs.<sup>34</sup> Having sexual intercourse with partners met online has also been directly linked to syphilis epidemics and HIV transmission;

in 2000 Klausner et al. reported a syphilis outbreak among gay men linked to an online chat room in San Francisco<sup>35</sup> and in 2003 Tashima et al. reported two cases of acute HIV infection acquired through meeting persons over the Internet.<sup>36</sup>

### INTERNET AS A MEDIUM TO DELIVER PREVENTIVE INTERVENTIONS FOR HIV/STI

Internet interventions have proven to be an efficacious method of delivering health-related information to a large number of people who report high-risk sexual behaviors and who would not otherwise seek care or be targeted for health related interventions.<sup>30</sup> Several approaches, including the creation of educational sites, appealing banner advertisements tailored to the participants, online partner notification, online counseling sessions, and online STI testing, have met with a certain amount of success.<sup>37,38</sup> However, effective strategies to retain participants enrolled on the Internet need to be studied, especially in longer follow-up studies. In 2004 Bull et al. lost 85% of participants to follow-up in a 3-month online longitudinal study<sup>39</sup> and in 2006 Bowen et al. lost 21% of participants in a 1-week online randomized controlled trial (RCT).<sup>40</sup>

Compared to noncomputerized methods of data collection, Internet-based surveys have the advantages of automated randomization of persons and questions, automated branching, calculation of complex algorithms, consistency checks, automated data collection, and easy inclusion of graphics, video, audio, and animation.<sup>41</sup> Additionally, it is easier to identify patterns predictive of nonintentional and inconsistent responding, logical impossibilities, and inconsistencies that may increase the internal validity of the studies. The Internet provides participants with the ability to access the survey at any time, which may increase the participation of people who do not respond through traditional approaches.<sup>41</sup> Furthermore, given that most Internet approaches ensure the anonymity of the participants, responses are less likely to be distorted in the direction of social desirability, which may improve the sensitivity of studies of HIV-risk related behaviors.<sup>41</sup> Regarding data quality, Internet data collection yields very few missing data points and avoids data transcription errors because the information collected can be exported directly to a statistical software program.<sup>41,42</sup>

### Online Videos, Instant Messaging, and E-mail Reminders

Video-based offline and online interventions have been proven effective in decreasing risk behaviors for HIV and in reducing STI acquisition.<sup>43,44</sup> An RCT among patients attending public STI clinics in the US found that participants assigned to a theory-based 23-minute video had significantly fewer STIs compared with a standard waiting room environment.<sup>43</sup> Another intervention conducted on the Internet found that MSM exposed to an online 9-minute video drama were 3 times more likely to disclose their HIV status to their sexual partners than MSM not

exposed to the intervention.<sup>44</sup> Video interventions are effective for several reasons: (i) they combine auditory-verbal and visual presentations and thus are more engaging to the participants; (ii) they can easily integrate behavioral theories and can display characters to whom participants can relate; (iii) most computers have the necessary software to display them; and (iv) once programmed, they require only minimal staff time.<sup>43,45</sup>

Another tool that is used for health interventions is human instant messaging in chat rooms. This tool has been used for several purposes: to recruit hidden MSM populations (e.g., Hispanic MSM in the US), to perform online interviewing and to provide HIV counseling sessions to high-risk populations.<sup>46,47</sup> Interestingly, over the last several years robots that perform automated online conversations have been developed. In 2008, Stieger et al. created a dynamic Internet-based automatic interviewing program via the instant messaging service. This program can perform multiple interviews simultaneously and the interviews can be branched, which means that each question depends on the answer given to the previous one.<sup>48</sup> An online address book offers the possibility of validating demographic data in order to evaluate data quality.<sup>48</sup> Also, Microsoft, in collaboration with the Ministry of Health in Spain, developed a robot called Robin; this robot is able to answer questions from adolescents about sexual and reproductive health 24 hours a day, 7 days a week and can be added as a contact in Windows Live Messenger.<sup>49</sup>

Other tools that have been used for HIV prevention are e-mail and cell phone text messaging. E-mail has been used for recruitment, retention, and partner notification. Bull and colleagues used e-mails for recruitment and retention in an Internet-based intervention oriented to increase condom use and HIV testing among MSM.<sup>39</sup> Wang and colleagues recruited MSM through e-mails in order to compare their profile with MSM contacted through chat rooms.<sup>50</sup> Regarding partner notification, participants of an Internet chat room were notified via e-mail messages about a syphilis cluster and were encouraged to seek medical evaluation.<sup>35</sup> The InSPOT website allows newly diagnosed patients with an STI/HIV infection to inform anonymously or confidentially their partners through an electronic postcard that they might have been exposed to an STI or HIV.<sup>51</sup>

### STUDIES FROM DEVELOPING COUNTRIES

In Latin America, Internet access is growing fast along with the use of the Internet as a tool to provide HIV preventive educational material.<sup>52</sup> The use growth from 2000–2009 in Central America, South America, and the Caribbean was 913%, 838%, and 1,534%, respectively.<sup>53</sup> Some examples of the use of the Internet for prevention are the creation of online educational sites oriented toward improving the knowledge of local healthcare providers about the HIV epidemic in Brazil, Russia, and Vietnam<sup>54–56</sup>; websites oriented toward educating the youth about the risk factors for HIV acquisition and the different modes of protection in Mexico, the Philippines, Nigeria, and South Africa<sup>57–61</sup>; online counseling sessions about sexual and reproductive health topics

in the Philippines and the use of subsidized computer access at commercial cybercafés as a mechanism to attract the young population in South Africa.<sup>60,61</sup> The Internet has also been used to provide young gay men with messages about HIV prevention and a better knowledge about their rights in Guatemala<sup>62</sup> and to build networks of MSM in areas with high discrimination against homosexuality such as the Caribbean.<sup>63</sup> In Brazil a website was developed to inform health and security staff of the penitentiary system about prevention and assistance programs related to HIV/AIDS,<sup>64</sup> and in China an online survey was used to assess knowledge and sexual risk behaviors for HIV/STI among MSM recruited from gay venues.<sup>65</sup>

Internet cafes or “cabinas publicas” may be an effective means for delivering low-cost prevention messages to a great number of people, especially those who are not being reached using more traditional methods.<sup>66</sup> Two interesting studies conducted in Peru have used the Internet for delivering HIV prevention interventions. In the first study, Internet showed to be an effective tool to reach an important group of high-risk MSM who are not being reached by traditional interventions and have not been tested for HIV. The study also showed that free HIV testing can be effectively utilized as an incentive for participation.<sup>67,68</sup>

The second study is a web-based RCT to assess the effect of a 5 minute health promotion video compared to a text-only intervention in increasing rates of HIV testing among MSM. The videos were customized for two audiences based on self-identification: either gay or non-gay men. The mean time of follow-up was 125.5 days (range 42–209 days). The conclusion of this study was that the health promotion video oriented to non-gay-identified MSM was effective in increasing HIV testing in this population, although the percentage of clinic attendance was only 11%. No effect was seen in the video oriented toward gay-identified MSM.<sup>69</sup>

## Information Systems for Public Health and Clinical Care in Developing Countries

Research projects are ongoing in several developing countries to build an infrastructure for national health information systems.<sup>70</sup> The experience working with electronic health records is limited in these countries because of structural deficiencies as well as considerable deficits in social policies, particularly those related to public healthcare.<sup>71</sup> A recent review reports that some researchers assume data collected in developing countries are incomplete, inaccurate, unreliable and not timely due to lack of personnel training, lack of quality control, and hardware and software compatibility.<sup>72</sup> Therefore, it is an increasing necessity to strengthen the health management information system in developing countries.

Several papers have described the experience of working with electronic health records. Some of them focused particularly on the implementation methodology, potentialities, description, and essential requirements,<sup>73,74</sup> reporting declines in registration errors, identification of absentees, and detection of risk factors

and complications. Other papers have reported the process and programmatic action of evaluation and management systems,<sup>75–77</sup> including extraction of selected information, identification of risk factors, and compliance monitoring. Finally, other reports have dealt with clinical decision-making support systems, particularly in chronic diseases.<sup>78,79</sup>

In the context of HIV/AIDS, the necessity of monitoring patient status and assessing treatment effectiveness requires methods to make information readily available and to facilitate adherence to guidelines.<sup>78</sup> In this part of the chapter, we review some experiences of using information systems for HIV/STI diagnosis, clinical management and provider training in resource-constrained settings.

## ELECTRONIC HEALTH RECORDS

Electronic health records have evolved rapidly, particularly in chronic disease management, due to the necessity of strategies to follow-up patients without generating excessive paperwork. These records can provide data for continuous quality improvement not only at the individual patient level, but also at the health system level.

In Peru, the Almenara Hospital, part of the Health Social Security System, has had a computerized registry for all inpatient and outpatient visits of HIV-infected individuals since mid-1990s. Through this system, basic data are collected such as demographic information, date of clinic visit, date of hospital admission, as well as diagnosis and treatment.<sup>80</sup>

In Zambia, Stringer et al. developed an electronic patient tracking system. The system tracks program performance indicators, tabulates pharmacy dispensation data, and generates lists of late patients needing follow-up. Late patients are sorted by their last CD4 cell count, so that priority can be given to tracking those who are most ill.<sup>81</sup>

The Academic Model for Prevention and Treatment of HIV/AIDS (AMPATH) is sub-Saharan Africa's first electronic health record system for the comprehensive management of HIV-infected patients.<sup>82</sup> It was the first system to offer comprehensive ambulatory HIV care in Kenya, and the health record system is currently in use in several countries in eastern Africa.<sup>83</sup>

Advances in electronic medical records have permitted using computerized clinical reminders to improve adherence to established clinical guidelines and alert health providers when an action is recommended.<sup>84</sup> In HIV care, these types of reminders were associated with opportune initiation of clinical practices.<sup>85</sup>

Lober et al. have developed and implemented an EMR that supports both individual and population healthcare of HIV-infected patients in Haiti since 2005. The system is now implemented in about 40 sites nationwide providing ART, and includes records for about 18,600 patients.<sup>86</sup>

Fraser et al. have described an electronic medical record system (HIV-EMR) to support HIV and tuberculosis treatment in remote areas of Haiti.<sup>87</sup> This system permits medical doctors to order drugs and laboratory tests and provides alerts according

to clinical status and test results. In rural Rwanda, Partners in Health has implemented the HIV-ERM system based on the OpenMRS architecture (HIV-EMR 2.0).<sup>88,89</sup>

In Malawi, the Baobab Health Partnership has developed an information system that has been used to issue nationally unique IDs to more than half a million patients across 3 urban sites. The system uses an innovative touch screen interface and also supports both voluntary counseling and testing and ARV treatment.<sup>90</sup>

Recently, Nucita et al. reported an electronic medical record system developed by the DREAM Project in sub-Saharan African countries. Today the DREAM software hosts data from more 73,000 patients and it is used in 10 countries in sub-Saharan Africa by thousands of professionals and is now in its fourth version.<sup>91</sup>

In the Peruvian PREVEN study, a web-based electronic report system for STI allows interviewers to enter their data directly and check past laboratory test results and medication prescriptions in real time.<sup>92</sup> NETLab is a web-based lab result registration system that allows patients and healthcare providers to access lab results, and affords decision and policy makers and lab managers' mechanisms to assess the speed and accuracy of lab results. NETLab was fully implemented in 2007 and national data are available in the database. The laboratory information system allowed connectivity of the 24 regional laboratories in the country and secure, password-protected access to results for all health professionals and many patients (especially HIV patients). In 2007, 112,086 laboratory tests had been registered and there are 950 people living with HIV and 1,269 health workers actively using the system.<sup>93,94</sup>

Health information technologies can help HIV-infected patients to manage their therapy regimens by themselves. Previous reports have demonstrated that web-based support sites can be useful for people living with HIV/AIDS by creating virtual support or affinity groups. Examples include VIHrtual Hospital, a telemedicine web system for improving integral care at home for chronic HIV patients via Internet<sup>95</sup>; CREAIDS (Center of Reference for AIDS), designed to improve adherence to ART<sup>96</sup>; and CARE+, created to support adherence to medication and HIV transmission risk reduction.<sup>97</sup>

## TELEHEALTH AND TELEMEDICINE

The terms telehealth and telemedicine have been used interchangeably; in general, telehealth includes clinical and non-clinical services (medical education, administration, and research) and telemedicine includes only clinical services. Telemedicine generally refers to the transmission of medical information via telephone, the Internet or other networks for the purpose of consulting, and sometimes remote medical diagnosis, treatment and procedures.

The use of telemedicine for training healthcare providers on HIV/STIs has been extensively used in developed countries<sup>98</sup> and is increasingly being used in developing countries.<sup>87,96,99</sup> To conduct real time consultations, telemedicine more frequently

consists of using innovative technology such as satellite technology and video-conferencing devices.

Telemedicine is important to improve care delivery in remote areas, especially where there are geographical barriers.<sup>98</sup> Telemedicine has increased access to care for remote populations using Internet, cell phones, or other network systems, and reduced access problems related to distance.<sup>100</sup> Although its use is limited in developing countries, telemedicine may support access to medical consultation for rural areas.

In rural areas, telemedicine may support access for teleconsultation. For example, TeleMedMail, written in Java, is a software application to facilitate store-and-forward telemedicine by secure e-mail of images from digital cameras.<sup>101</sup> However, none of the telemedicine and e-health systems used in developed countries are ready to be deployed across a developing country as a whole.<sup>102</sup>

HOPE program is a collaborative initiative including healthcare professionals in the United States, Europe, Africa, Asia, and the Caribbean.<sup>103</sup> This program uses an Internet-conferencing technology to conduct interactive case conferences with healthcare professionals throughout the world.<sup>103</sup> This technology has been shown to be a feasible, cheap, and effective model for providing clinical support, consultative advice and continuing training and education to healthcare workers dealing with HIV-infected patients in resource-poor countries.

The Institute of Tropical Medicine, Antwerp, has created a telemedicine system (<http://telemedicine.itg.be>) for healthcare workers working in resource-limited settings to train them in the use of ART and AIDS care delivery. Specialists offer expert advice to their colleagues through an HIV/AIDS discussion forum covering topics such as ART and the management of opportunistic infections.<sup>104</sup>

## ICT to Support Education and Professional Development for Healthcare Workers Treating HIV/STIs in Developing Countries

Continuing Education (CE) for healthcare workers is widely available in developed countries. Healthcare workers can participate in CE courses in order to stay updated on new evidence and practice their skills. The available traditional CE programs for health professionals have generally shown small impact on sustained improvement in knowledge, and a failure to translate improvements in knowledge into improved healthcare provider practices or improved patient outcomes.<sup>105–107</sup> In many developing countries, CE programs have additional limitations. CE is provided largely in major urban settings and not easily accessible to most healthcare providers.<sup>108–110</sup>

Technology is playing a growing role in CE. The use of computers, Internet, and other forms of technology provides the opportunity for self-directed and problem-based learning-elements lacking in traditional CE methods. In recent years many organizations have been using technologies to improve the training and upgrading skills of healthcare providers. Internet-based CE is

an alternative to traditional CE, and has increased exponentially in recent years. Technological advances on the Internet now allow inclusion of complex information on Web sites, interactive links (bulletin boards, chat rooms, instant messaging, and discussion), video, images, and sounds. Thus, it is feasible to illustrate real clinical situations and encourage realistic problem solving. From both a practical and a theoretical perspective, Internet-based CE offers certain advantages over traditional CE.<sup>110–114</sup> These advantages include real-time interactivity, flexibility (location and time), potential for reinforcement (since it is continuously available), adjustability to adult learning approaches, potential for standardized materials of high quality, potential low cost, links to other resources, and accessibility to providers outside major urban centers.

Many training centers from nongovernmental, public, and private organizations have created Internet-based training programs on HIV/STIs for healthcare workers.

The National Network of STD/HIV Prevention Training Centers (NNPTC) is a group of regional centers constituted by health departments and universities funded by CDC (Centers for Disease Control and Prevention). Some members of the NNPTC offer online training to healthcare providers working in developing countries ([http://depts.washington.edu/nnptc/online\\_training/index.html#chlamydiaeasebased](http://depts.washington.edu/nnptc/online_training/index.html#chlamydiaeasebased)).

Some examples of the novel applications of comprehensive Internet-based training using interactive cases included: the HIV web study, the STD Case Series, and the Chlamydia Case-based Training.

Organizations from developing countries are also developing initiatives to create Internet-based training programs. In China, the Chinese National AIDS Prevention and Control Center (<http://www.chinaids.org.cn/>) developed an HIV/STI training course.<sup>115</sup> In Peru, the Universidad Peruana Cayetano Heredia has created an interactive course “STD/Serie de Casos” (<http://www.proyectopreven.org>) in Spanish using clinical cases to train healthcare providers from different regions for syndromic management of sexually transmitted diseases.<sup>116</sup>

## COMPUTER-BASED TRAINING ON HIV/AIDS

Computer-based training (CBT) is a method of training that uses computers. Participants learn by executing special programs. CBT programs include high levels of interaction and simulated environments. CBT is often delivered via CD-ROM. Many institutions are working to develop CBT programs for healthcare workers in developing countries.<sup>117,118</sup>

The International Training and Education Center on HIV (I-TECH) (<http://www.go2itech.org>) works in 10 countries around the world (Botswana, Ethiopia, Guyana, Haiti, India, Malawi, Mozambique, Namibia, South Africa, Tanzania). I-TECH has created training programs and developed a wide variety of media products. CD-ROMs and websites containing videos in multiple languages and training toolkits offer resources for developing, delivering, and evaluating training on HIV-related topics.

The WHO Reproductive Health Library (RHL) (<http://www.who.int/hrp/rhl/>), an electronic review journal published by the Department of Reproductive Health and Research at World Health Organization, compiled the best available evidence on sexual and reproductive health including HIV and STI and presents it as practical actions for clinicians and policy-makers. The information including training videos to help master clinical skills is distributed free through the RHL CD-ROMs to healthcare workers, primarily in under-resourced settings.

I-Med Exchange, International Association of Physicians in AIDS, created an Internet-based training program.<sup>119</sup> I-Med Exchange provides training to healthcare workers in 4 countries: South Africa, Lesotho, Swaziland, and Botswana.<sup>119</sup> The programs include presentations of clinical cases. Participants can access them via Internet or by using CD-ROMs. The program uses videos and chat rooms and offers the opportunity to ask questions of experts.<sup>119</sup>

## Access to Information

The Internet now allows healthcare workers to access the latest relevant information from journals without the need of paper based journal subscriptions or library access. Although universal access to information for health professionals is a prerequisite for meeting the Millennium Development Goals and achieving Health for All,<sup>120</sup> lack of access to information remains a major barrier in developing countries.<sup>121,122</sup> Despite this limitation, there are many successful initiatives in developing countries that might be expanded and replicated.

The WHO Sexually Transmitted Diseases Diagnostic Initiative<sup>123</sup> ([http://www.who.int/std\\_diagnostics](http://www.who.int/std_diagnostics)) publishes summaries and reviews related to new developments in laboratory and field diagnosis of STIs providing key information to healthcare providers around the world, particularly to those from developing countries.

BIREME (<http://www.bireme.org>), the Latin American and Caribbean Centre for Health Sciences Information, founded by an agreement between the Pan American Health Organization (PAHO)/WHO and the Brazilian Government. BIREME created SciELO (the Scientific Electronic Library Online) (<http://www.scielo.org>) the first and largest data based of free full-text access to health research information. BIREME created LILACS (<http://lilacs.bvsalud.org>), which indexes journals from Latin America and the Caribbean. BIREME also created the Virtual Health Library (<http://www.bvsalud.org>), which provides free online access to evidence-based resources that support healthcare decisions.

EMRO, World Health Organization Eastern Mediterranean Regional Office, created a database of books and journals from the region and created the EMRO Index Medicus that index more than 310 journals in the region. It is published in print, CD-ROM, and on the Internet.

The Association for Health Information and Libraries in Africa (<http://www.ahila.org>) and the African Index Medicus (<http://indexmedicus.afro.who.int/>) are other interesting initiatives.

Health InterNetwork Access to Research Initiative (HINARI) (<http://www.who.int/hinari/>), a WHO initiative, provides free access to approximately 2,300 online journals.

## Conclusion

The information and communication technologies (ICT) reviewed in this chapter provide people with different choices that can be applied in different patients to support HIV and STI prevention and care. Although ICT are being used for the prevention and control of HIV and STI, there are still several applications, such as the combined use of Internet and cell phones or the use of instant messaging systems, whose effectiveness in increasing HIV testing needs remains to be studied. Much less have been done in the use of ICT for prevention and care in other STIs. ICT have become ubiquitous even in resource-constrained settings, thus more research in their use for the prevention, control and treatment of HIV and STI in those countries needs to be conducted. While a variety of information and communication technology tools are in various stages of use for HIV/STI prevention, relatively few areas have accumulated a critical mass of evidence about effectiveness and sustainability. However, some of that evidence is compelling, and the potential for future uses appears large. Application to some areas of practice and research are nascent and evaluation of these tools would benefit from rigorous methodological designs.

## Acknowledgment

The authors gratefully acknowledge the editorial assistance of Kristen Heitzinger.

### Summary

This chapter starts by describing two applications that we consider have the most potential to support HIV and sexually transmitted infections (STI) care in developing countries: mobile devices and the Internet. Then we describe some notable examples of information systems used for clinical care in developing countries. Finally, we present how information and communication technologies (ICT) are supporting education and professional development for healthcare workers treating HIV/STI in developing countries.

## Vaccines for Sexually Transmissible Infections

Anna McNulty

### Introduction

Vaccines play a special role in the health and security of nations. The World Health Organization (WHO) cites immunization and the provision of clean water as the two public health interventions that have had the greatest impact on the world's health, and the World Bank notes that vaccines are among the most cost-effective health interventions available. Over the past century, the integration of immunization into routine healthcare services in many countries has provided caregivers with some degree of control over disease-related morbidity and mortality, especially among infants and children.

The terms *vaccination* and *immunization* are often used interchangeably, although technically the former denotes the administration of a vaccine, whereas the latter refers to the induction or provision of immunity by any means, active or passive. Thus, vaccination does not guarantee immunization, and immunization may not involve vaccine.

Because the immune response is genetically controlled, all individuals cannot be expected to respond identically to the same vaccine. Additional vaccine constituents (adjuvants) affect immunogenicity, efficacy, and safety and may render one formulation superior to another formulation of the same antigens.

### Approaches to Active Immunization

The two standard approaches to active immunization are (i) the use of live, generally attenuated infectious agents (e.g., measles virus); and (ii) the use of inactivated agents (e.g., influenza virus), their constituents (e.g., *Bordetella pertussis*), or their products, which are now commonly obtainable through genetic engineering (e.g., hepatitis B vaccine). For many diseases (e.g., poliomyelitis), both live and inactivated vaccines have been employed, each offering advantages and disadvantages.

Live attenuated vaccines consisting of selected or genetically altered organisms that are avirulent or dramatically attenuated, yet remain immunogenic, typically generate long-lasting immunity. These vaccines are designed to cause a subclinical or mild illness

and an immune response that mimics natural infection. They offer the advantage of microbial replication *in vivo*, which simulates natural infection; they may confer lifelong protection with one dose; they can present all potential antigens, including those made only *in vivo*, thus overcoming immunogenetic restrictions in some hosts; and they can reach the local sites most relevant to the induction of protective immunity.

Nonliving vaccines typically require multiple doses and periodic boosters for the maintenance of immunity. The exceptions to this rule are the pure polysaccharide vaccines, whose effects cannot be boosted by additional exposures because polysaccharides do not elicit immunologic memory. Nonliving vaccines administered parenterally fail to induce mucosal immunity because they lack a delivery system that can effectively transport them to local mucosal antigen-processing cells. Despite their many advantages, live vaccines are not always preferable. STIs are most likely to infect via the mucosa in the majority of exposed people. It therefore seems logical to develop vaccines that are designed to be administered via the mucosa or to stimulate mucosal immunity to prevent or combat these infections.<sup>1</sup>

### POSTEXPOSURE IMMUNIZATION

For certain infections, active or passive immunization soon after exposure can prevent or attenuate disease expression. For example, giving either measles immune globulin within 6 days of exposure or measles vaccine within the first few days after exposure may prevent symptomatic infection. Proper immunization for tetanus plays an important role in dirty-wound management. The need for active immunization—with or without passive immunization—depends on the wound's condition and the patient's immunization history. Similarly, for persons who have not been actively immunized, administration of hepatitis A immune globulin within 2 weeks of exposure to hepatitis A virus is likely to prevent clinical illness. Evidence also supports the efficacy of human hepatitis B immune globulin in preventing disease after exposure.

## Vaccines for Sexually Transmitted Infections

Vaccination is potentially one of the most effective strategies to reduce the incidence of STIs. In general for vaccination as a strategy to be successful at a population level, the vaccine must be safe, effective, and accessible, resulting in high levels of coverage.

There are, however, differences between vaccination strategies that will be effective for childhood infections versus STIs. Firstly, the risk of acquiring an STI is limited to the sexually active population and it is generally women who suffer complications of infection. In addition the risks of acquiring and transmitting an STI are extremely variable across the population whereas this is not the case for childhood infections.<sup>2</sup> Thus, it is possible that vaccines with only partial efficacy or only vaccinating one sex, for example human papillomavirus (HPV) vaccination, will be effective strategies.

### Barriers to Vaccine Uptake

In general terms, barriers to vaccination center around health beliefs and health behaviors. These include perceived susceptibility to the disease, concerns regarding the perceived benefits and efficacy of vaccination, and beliefs about disease severity. In addition with the increasing number of infant vaccinations now recommended in many jurisdictions, the complexity of the vaccine schedule can be a barrier to both vaccine uptake and completion.<sup>3</sup>

In resource poor settings cost is the major barrier to vaccine implementation. The Global Alliance for Vaccines and Immunization (GAVI) is a successful partnership between public and private stakeholders established in 2000 with the aim of increasing the availability of vaccines through innovative financing in 72 of the world's poorest countries. The WHO's Expanded Program on Immunization (EPI) led to the concept of integrating maternal and child health with immunization programs. When done successfully between compatible programs, this has resulted in less duplication of services and competition for resources.<sup>4</sup>

One of the specific barriers with regard to vaccines against STIs is a seeming endorsement of a decline in sexual moral values. This argument has been applied in the implementation of the HPV vaccination in adolescent girls in a number of countries. However, available data suggest sexual risk does not increase as a result of vaccination.<sup>5</sup> In many countries the HPV vaccine has been marketed as a vaccine to protect against cervical cancer with little mention made of sexual transmission of HPV.

Vaccine acceptance has been shown to be influenced by the attitude of the healthcare provider and the patient's perception of this attitude. Thus, an important component in the development of health promotion campaigns for STI vaccines is education of healthcare providers.<sup>3</sup>

### Strategies for Vaccine Development

The important factors which must be considered when determining the feasibility of developing a vaccine are:

- the nature of the organism (its complexity),

- the nature of the infection (acute or chronic),
- the host's ability to develop natural immunity after infection,
- whether the organism is cultivatable,
- the degree of antigenic diversity, and
- the availability of a suitable animal model.

In analyzing these factors, it would appear that most STI pathogens are structurally complex and confer limited, if any, immunity following infection. Many of these pathogens show significant antigenic diversity, which enables the pathogen to avoid the host's immune system, and may be a major obstacle in vaccine development. Because humans are the only natural host for most STI pathogens, it has been difficult to find an animal model that adequately imitates all aspects of the human disease. However, except for *T. pallidum* and HPV, all STI pathogens are cultivatable, which gives us a reason for hope in the challenging task of developing vaccines against STI pathogens.

### Potential Vaccination Strategies

The fact that the classic STI agents are pathogenic only in humans favors their eradication. However, the tendency of certain STI pathogens (gonococcus, chlamydia, HSV) to cause subclinical or asymptomatic infection in some individuals indicates that these organisms can effectively avoid the host immune system.

For successful implementation of any vaccination strategy the target population must be carefully defined and its easy accessibility assured.

Different STIs may require different vaccine strategies. For eradication or elimination, universal vaccination is required (with a vaccine that provides lifelong immunity), which is usually administered during infancy or childhood. However, this is an expensive strategy and might not be widely accepted. Containment could probably be accomplished by selective immunization of high-risk population (adults in sexually active years).

An alternative strategy would be selective vaccination, i.e., a vaccine that would be effective in only males or females. Immunization of one would probably, as a result, prevent infection in the other. A disadvantage of selective vaccination is that it is often difficult to identify or access groups most at risk and ensure adequate coverage of vaccine. However, a selective STI vaccination strategy could mimic strategies being considered for HIV vaccination in developing countries. These strategies include targeting urban adolescents and young adults (10–19 year old) attending school, and women of childbearing age accessed by WHO Expanded Program on Immunization (EPI) to receive the tetanus toxoid.<sup>4</sup> A strategy to accomplish maximum coverage should focus at two different goals: (i) containment, by targeting adults in the sexually active period (most likely 15–49 year old, with priority to 15–25 years of age) to ensure rapid “mopping up” of those people at risk of infection; while (ii) aiming at elimination by ensuring integration of vaccination into existing programs, such as EPI, and school immunization programs to replace the “mopping up strategy” once those immunized at young ages reach sexual activity.

## Hepatitis B Vaccine

Hepatitis B vaccination is highly effective in preventing both hepatitis B and D. Recombinant hepatitis B vaccine has now replaced the use of plasma derived vaccines. It is available in adult and child formulations and in combination with hepatitis A vaccine. It is also available as part of a polyvalent vaccine for infant immunization.

### EFFECTIVENESS IN CLINICAL TRIALS

The original plasma derived hepatitis B vaccine was demonstrated to be effective in high-risk men studied in 2 large randomized blinded placebo controlled studies in the United States in the late 1970s. Participants in these studies received doses of either 20 or 40 µg at 0, 1, and 6 months and after the third dose more than 95% of recipients had anti-HBs titers  $\geq 10$  IU/L.<sup>6</sup>

A third-generation hepatitis B vaccine containing pre S1 and pre S2 has been developed and trialled. Vaccines containing pre S1 and pre S2 are thought to stimulate a more robust immune response, particularly important for poor and non responders to the currently commercially available vaccines.<sup>4,7</sup>

### EFFECT AT REDUCING DISEASE BURDEN

A Cochrane review of hepatitis B vaccination in those not previously exposed or of unknown exposure status reviewed 12 studies that met their inclusion criteria.<sup>9</sup> Most of the studies were of poor quality. In four of these studies, Hepatitis B vaccination reduced the risk of developing Hepatitis B surface antigen by 88% and for hepatitis B core antibody by 62% when compared with no vaccination. Previous Cochrane reviews have shown benefit of hepatitis B vaccination in high-risk groups such as healthcare workers and in infants born to mothers with chronic hepatitis B.

### LOW ENDEMICITY (<2% POPULATION HBsAg POSITIVE)

The WHO recommends universal infant vaccination in this population as the most effective method of reducing hepatitis B prevalence.<sup>10</sup> In low-prevalence countries a significant proportion of chronic infection is acquired via childhood transmission. Selective screening of mothers, and vaccination of at-risk infants, may miss a significant proportion of those at risk, as those most likely to be infected with hepatitis B may be those most likely to have minimal or no antenatal care.

### MODERATE ENDEMICITY ( $\geq 2$ – $< 8$ % POPULATION HBsAg POSITIVE)

Universal infant vaccination is recommended in countries with a moderate prevalence of hepatitis B. The benefits of this approach have been demonstrated in a number of different countries. In Gambia, following the introduction of universal infant vaccination, the rate of chronic HBsAg carriage decreased from 10.3% to 0.6%. Similar decreases have been noted in Alaska, Italy, China, Thailand, and Saudi Arabia.

### HIGH ENDEMICITY ( $\geq 8$ % POPULATION HBsAg POSITIVE)

Universal infant vaccination commenced in Taiwan in 1987 with a catch up program for children and adolescents introduced over subsequent years. Over 90% of infants complete the vaccination course and numerous studies have demonstrated a dramatic impact on hepatitis B epidemiology in Taiwan. In addition to decreasing the rate of HBsAg carriage in those under 15 years of age from 9.8% to 0.7% in 1999, there has been a 75% decrease in the incidence of hepatocellular carcinoma in children 6–9 years old since the national vaccination program began.<sup>11</sup>

A significant benefit has already been seen within 20 years of the introduction of universal infant vaccination and this will increase as the vaccinated cohort ages.

### COST EFFECTIVENESS

Cost effectiveness of hepatitis B vaccination increases with the use of combination polyvalent vaccines from the infant/childhood vaccination schedule which incorporate hepatitis B. Combination polyvalent vaccines are often the same price or cheaper than monovalent vaccines.<sup>12</sup>

### HIGH, MODERATE, AND LOW ENDEMICITY COUNTRIES

Universal infant vaccination is cost effective.<sup>13</sup>

### VERY LOW ENDEMICITY COUNTRIES ( $\leq 0.5$ % POPULATION HBsAg POSITIVE)

Cost effectiveness studies in this setting have produced contradictory results depending on the type of evaluation conducted. The ability to achieve sufficient coverage with selective vaccination needs to be assessed, however, if high, this strategy is currently considered more cost effective than universal infant vaccination.

### HEPATITIS B VACCINATION IN HIV POSITIVE INDIVIDUALS

A number of different studies have reported lower efficacy of hepatitis B vaccination in HIV positive individuals with between 17.5 and 62% developing a protective antibody response even in the era of highly active antiretroviral therapy.<sup>14</sup> Those less likely to respond have a lower nadir CD4 count than those who do respond. Conversely, those with undetectable HIV RNA are more likely to respond to hepatitis B vaccination. In those who are HIV positive, hepatitis B surface antibody levels are lower than in HIV negative individuals and decline more quickly. For this reason a number of guidelines recommend using hepatitis B vaccine at twice the dose recommended for immunocompetent individuals and to check hepatitis B surface antibody levels annually.

In those who fail to respond to the initial course of vaccination, a repeat course will result in seroconversion in up to 51%.<sup>14</sup>

## Hepatitis A Vaccine

Vaccination against hepatitis A has been available since 1994. There are currently 5 hepatitis A vaccines available internationally. Three of these are live attenuated vaccines. A virosomal hepatitis A vaccine has also been developed and trialled but is not widely available. Vaccines are licensed for both adults and children and there is also a combined hepatitis A and B vaccine.

### EFFECTIVENESS IN CLINICAL TRIALS

Immunization following a 2 dose schedule at 0 and 6 months produces neutralizing antibodies which protect against both infection and disease. Clinical effectiveness has only been studied in children, however it is reasonable to assume that adults would develop similar protective levels of immunity.

More than 88% of adults and children acquire a protective antibody level within 2 weeks of the first injection and 99% at 1 month following the first injection. One month after the second dose 100% had protective immunity.<sup>15,16</sup>

### EFFECT AT REDUCING DISEASE BURDEN

In areas of high endemicity the impact on clinical disease burden is small as most infection prevented is asymptomatic childhood disease. In countries of moderate and low endemicity the impact is greater as adult disease is more likely to be symptomatic. The introduction of universal infant hepatitis vaccine in high-incidence areas in the US and in Israel led to a rapid reduction in disease incidence in both children and adults reflecting the impact of herd immunity.<sup>7</sup>

Targeted hepatitis A vaccination is effective at reducing disease burden when given in “closed communities” due to both individual and herd immunity. Hepatitis A vaccination postexposure has also proven effective during hepatitis A outbreaks.

### COST EFFECTIVENESS

In considering the introduction of large scale vaccination programs the public health impact of hepatitis A needs to be weighed up against that of other vaccine preventable diseases.

### HIGH ENDEMICITY

In the generally resource poor countries, hepatitis A acquisition in childhood is almost universal and generally asymptomatic. Consequently hepatitis A is a minor public health issue and large scale immunization efforts are not recommended.<sup>16</sup>

### MODERATE ENDEMICITY

Universal infant vaccination is most likely to be cost effective in such countries however, costs associated with hepatitis A infection and a hepatitis A vaccination vary widely making generalizability of study findings difficult.<sup>17</sup> A number of countries

(for example, Israel, USA, Italy, Chile) have introduced universal infant vaccination and found it to be cost effective particularly in high-incidence areas within the country. Cost effectiveness is increased when a combined hepatitis A/hepatitis B vaccine is used.<sup>17</sup>

### LOW ENDEMICITY

A number of economic evaluations have looked at targeted vaccination and in most of these studies this approach is not cost effective. Vaccination of travelers to moderate or high endemicity countries is recommended.<sup>16</sup> The cost effectiveness of screening and vaccinating men who have sex with men (MSM) is unknown, however, one US study argued that replacing hepatitis B vaccination with hepatitis A and B in all STD clinic patients was cost-effective.<sup>18</sup>

## Human Papillomavirus Vaccine

There are currently 2 licensed prophylactic HPV vaccines. Both vaccines use virus like particles (VLPs) of the recombinant major capsid (L1) protein of HPV to stimulate a protective immune response to the relevant HPV types. Since the VLPs contain no viral DNA they cannot infect cells or reproduce. Gardasil is a quadrivalent vaccine (Merck and Co, Inc) and induces a protective response against HPV types 16,18, 6,11 while Cervarix (GlaxoSmithKline) is a bivalent vaccine against types 16,18. HPV types 16, 18 are responsible for ~70 % of cervical cancers worldwide and HPV 6,11 are responsible for ~90% of genital warts. Both vaccines are highly immunogenic and stimulate higher antibody levels than those seen after the clearance of natural HPV infection. Both vaccines have a 3 dose schedule over 6 months and require storage at 2–8°C. Studies in adolescent boys 9–15 years of age have demonstrated antibody responses similar to those found in adolescent girls.<sup>19</sup>

### EFFECTIVENESS IN CLINICAL TRIALS

Clinical trials in women have demonstrated more than 90% efficacy in the prevention of infection, persistent infection and high-grade cervical lesions in those who adhered to the trial protocols (Table 15.1).<sup>20</sup> Follow-up data are available for at least 6 years in some cohorts. The quadrivalent vaccine also protected against external genital warts and vulval (VIN) and vaginal (VaIN) intraepithelial neoplasia.<sup>21</sup> Entry into the clinical trials was restricted by age, number of sexual partners, and pre-existing history of cervical abnormalities.

Clinical trials have shown that the vaccine is effective in men. A study of 4065 men aged 16–26 years in a randomized placebo controlled trial demonstrated vaccine efficacy against any HPV 6/11/16/18 external genital lesion (EGL) of 90.4% and against persistent infection of 85.6%.<sup>22</sup> A smaller study in 602 MSM demonstrated vaccine efficacy of 79% and 94.4% against any HPV 6/11/16/18 EGL and persistent infection, respectively.<sup>23</sup>

**Table 15.1:** Summary of Clinical Trial Effectiveness, Population Level Impact and Cost Effectiveness of Currently Available STI Vaccines

Clinical trials	Hepatitis B	Hepatitis A	Human papilloma virus
	Highly effective	Highly effective	Highly effective (adolescent girls and young women <26 years)
Population level impact	Universal infant vaccination effective in all settings	<b>Low/moderate endemicity:</b> Effective at reducing disease incidence <b>High endemicity:</b> Less impact if infection acquired predominantly in childhood	Anticipated to have maximal impact in countries with inadequate or no cervical screening programs
Cost effectiveness	Highly cost-effective in all settings	<b>Low endemicity:</b> Depends on risk <b>Moderate endemicity:</b> Universal childhood vaccination cost-effective <b>High endemicity:</b> Unlikely	<b>Women:</b> Anticipated to be cost-effective especially if increased age at first cervical screen and/or increased screening interval <b>Men:</b> Insufficient data

Other populations to be studied include infants and immune compromised individuals.

Work is ongoing to monitor the duration of protective immunity, examine alternative vaccination schedules and monitor the safety profile of the vaccines. The impact of HPV vaccination on cervical screening programs is being examined in various countries.

### EFFECT AT REDUCING DISEASE BURDEN

In resource poor countries where the incidence of cervical cancer is higher due to a lack of, or inadequate cervical screening programs, the impact of HPV vaccines will be greater. There is evidence that both vaccines<sup>24</sup> offer partial protection against genetically related oncogenic nonvaccine HPV types 31/33/45/52/58. Cervical intraepithelial neoplasia (CIN) 1-3 and adenocarcinoma *in situ* due to these types was reduced by 43.6% following vaccination with the quadrivalent vaccine in women without pre-existing infection with these HPV types.<sup>25</sup> Cross protection against these nonvaccine oncogenic HPV types that may be responsible for up to 20% of cervical cancers will add further to the anticipated reduced incidence of cervical cancer. Programs for vaccine implementation in resource poor countries are currently being developed.<sup>26</sup>

In those countries that elect to use the quadrivalent vaccine there will be a significant reduction in healthcare utilization for the management of external genital warts, however, it is too early to quantify the impact on a large scale. Early evidence of benefit exists in Australia where government funded quadrivalent HPV vaccination for 11–12-year-old girls and a catch up program for girls and women up to 26 years of age commenced in April 2007. A study at Melbourne Sexual Health Centre showed a decrease in genital wart diagnoses in new patients (heterosexual women <28 year old and heterosexual men) when comparing the years 2004–7 and 2008 suggesting that comprehensive vaccination of females can produce early benefits in both women and heterosexual men.<sup>27</sup>

The licensed HPV vaccines have no impact on natural history or clinical disease in those who have already acquired the vaccine HPV type prior to vaccination.<sup>28</sup> However, some tantalizing

early work has been done utilizing a different type of HPV vaccine for therapeutic purposes. In a study by Kenter et al.<sup>29</sup> the immunogenicity and efficacy of a vaccine containing HPV-16 E6 peptides and 4 HPV-16 E7 synthetic peptides in the treatment of grade 3 vulvar intraepithelial neoplasia was examined. Of the 20 women treated, 15 of 19 had a clinical response at 12 months of follow-up and 9 of 19 had complete remission at 12 months of follow-up. Clinical response was associated with a stronger vaccine induced T cell response.

### HPV VACCINE RECOMMENDATIONS

The HPV vaccine is routinely recommended for 11 and 12 year-old girls. The vaccine series can be started at 9 years of age. Catch-up vaccination is recommended for 13 through 26 year old females who have not yet received or completed the vaccine series.

Ideally, females should be vaccinated before onset of sexual activity, when they may be exposed to HPV. However, sexually active females may also benefit from vaccination since few young women are infected with all HPV types targeted by the vaccine. Females who already have been infected with one or more HPV types would still get protection from the vaccine types they have not acquired. Currently, there is no test available for clinical use to determine whether a female has had any or all of the HPV types targeted by the vaccine.

#### The HPV vaccine can be given to females who:

- are lactating;
- have minor acute illnesses, such as diarrhea or mild upper respiratory tract infections, with or without fever;
- have an equivocal or abnormal Pap test, a positive Hybrid Capture II® high-risk test, or genital warts. However, women should be advised that data do not indicate that the vaccine will have any therapeutic effect on existing Pap test abnormalities, HPV infection or genital warts; and
- are immune compromised, either from disease or medication. However, the immune response to vaccination and vaccine efficacy might be less than in immune competent females.

**The HPV vaccine should not be given to females who:**

- are pregnant. Although the vaccine has not been causally associated with adverse pregnancy outcomes or adverse effects on the developing fetus. However, data on vaccination in pregnancy are limited;
- have a history of immediate hypersensitivity to yeast or to any vaccine component; and
- have moderate or severe acute illnesses. In these cases, girls/women should wait until the illness improves before getting vaccinated.

**HPV VACCINE ADMINISTRATION**

The vaccine should be delivered through a series of three intramuscular injections over a 6-month period. The second and third doses should be given 2 and 6 months after the first dose. The vaccine can be administered at the same visit as other age-appropriate vaccines.

**COST EFFECTIVENESS**

A number of modeling studies in developed countries have demonstrated cost effectiveness when all adolescent girls are vaccinated particularly if this leads to an increase in the age when cervical screening commences and/or a reduction in the frequency of cervical screening.<sup>30</sup>

In resource poor countries, the cost of the vaccine will be the major determinant of cost effectiveness. Global agencies purchasing large vaccine volumes have the ability to negotiate lower prices, however, individual countries will still need to consider program costs in the light of competing health priorities. In addition, since the vaccine is administered in preadolescents, program costs will be higher as resource poor countries in general, do not have specific health programs for this age group. A number of demonstration projects are being implemented in resource poor settings to examine different models of vaccine delivery.

There are currently insufficient data on the cost effectiveness of vaccinating men. However, mathematical modeling suggests that with high coverage rates in women there is little additional benefit in vaccinating men in order to prevent cervical cancer in women. The direct cancer prevention effects in men would be lower than in women due to the lower incidence of HPV related cancers in men.

**Herpes Simplex Virus Vaccine**

The prospect for developing a vaccine against HSV-2 that could provide sterilizing immunity is thought to be unrealistic. The goals of the vaccines under development are rather to prevent the establishment of latent infection by blocking access of the virus to sensory ganglia, to reduce the severity of the symptoms, and/or to reduce the frequency of recurrences. There has been more significant progress in the development of a vaccine against herpes simplex virus type 2 (HSV-2) infection. A HSV-2 glycoprotein D subunit vaccine developed by GlaxoSmithKline (GSK) proved effective only in women who were seronegative for both HSV-1

and 2 at baseline.<sup>31</sup> It was not effective in men. The subset of women in whom the vaccine was effective experienced a 73% reduction in genital herpes disease compared with controls.<sup>31</sup> A further study to examine the impact of this vaccine in more than 8000 women was recently terminated when no effect was found.<sup>32</sup> Studies of HSV vaccine effectiveness need to distinguish between protection against disease and protection against infection. An HSV-2 vaccine that prevents disease but not infection will need to reduce transmissibility through a reduction in viral shedding to be effective at a population level.<sup>33</sup>

A novel, live attenuated HSV-2 candidate vaccine has been developed by Xenova/GSK using a replication-impaired virus mutant that lack the gene of the essential glycoprotein gH (ICP8 gene mutation) as a disabled infectious single cycle (DISC) virus vaccine. The vaccine was tested in phase II trials in the USA as a therapeutic vaccine in HSV-2 seropositive symptomatic patients. It was well-tolerated and induced neutralizing antibodies and cytotoxic T lymphocytes (CTL) in 83% of the vaccinees, but no difference in time to recurrence and no difference in virus shedding were observed as compared with controls. The development of the DISC vaccine has been refocused toward its use as a prophylactic vaccine.

- Another live, replication-impaired vaccine is currently under development by Avant Immunotherapeutics. Other viral mutants that are defective for replication and impaired for establishment of latency, such as mutant dl5–29, are at a preclinical stage of development.
- A live attenuated vaccine based on a replication-competent ICP10 mutant of HSV-2 developed by AuRix is in phase II clinical study.

For the developing world where the acquisition of HSV-1 in childhood is almost universal, a vaccine that is effective only in those seronegative to HSV-1 and 2 would be of minimal benefit. Work is continuing on the development of alternative models for an HSV vaccine.

**Vaccines Against other STIs**

There has been little progress in the development of vaccines against the bacterial pathogens *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Treponema pallidum*, *Haemophilus ducreyi*, and *Klebsiella granulomatis*. Work is ongoing to understand the biology, pathogenesis and immune responses to these organisms in both animal models and humans.

**CHLAMYDIA TRACHOMATIS**

A safe vaccine administered prior to adolescence that is effective through childbearing age would have a significant impact on the spread of the disease. The lack of a suitable animal model and the difficulties in genetic manipulation of the bacterium has hampered progress in the field. The vaccine that has been tried is a subunit vaccine (TRACVAX) which has been tested in a randomized phase I trial designed to assess the safety and

immunogenicity of the candidate vaccine and a surface-exposed antigen termed polymorphic membrane protein D (PmpD) which induces neutralizing antibodies *in vitro* in animal models.

Identification of potential vaccine antigens is today an active area of research which is greatly helped by the availability of the complete *C. trachomatis* genome sequence, allowing for the identification and testing of candidate proteins based on their similarity to proteins important in protective immunity against other bacterial pathogens.

## NEISSERIA GONORRHOEAE

The lack of a suitable animal model and the considerable antigenic variability of the bacterium have hampered the development of a vaccine for gonorrheal disease. Attachment of gonococci to mucosal cells is mediated in part by the pili, and it was found that rabbit antibody to pili reduces attachment of the bacteria to mammalian cells. Pilin was therefore chosen as the most likely vaccine candidate and tested for efficacy in military recruits and in volunteers challenged urethrally. This approach was met with some success, but protection was strain-limited, due to the high rates of antigenic variation of pili. Porin also was studied as a vaccine antigen but the induced anti-porin antibodies were not bactericidal.

## HIV Vaccines

The development of a safe and effective vaccine is hampered by the high genetic variability of HIV, the lack of knowledge of immune correlates of protection, the absence of relevant and predictive animal models, and the complexity of the implementation of efficacy trials, especially in developing countries. The first phase I trial of an HIV vaccine was conducted in the USA in 1987. Since then, more than 30 candidate vaccines have been tested in over 80 phase I/II clinical trials, involving more than 10,000 healthy human volunteers. Two phase III trials have been carried to completion and a third one is in progress. The different vaccine types that have been used are:

- live attenuated vaccines,
- subunit vaccines, and
- live recombinant vaccines.

## OTHER VACCINAL APPROACHES

Induction of persistent HIV gag-specific CD8<sup>+</sup> CTL responses was attempted in a trial involving immunization with a fusion protein comprising the HIV p24gag protein and detoxified *Bacillus anthracis* lethal factor. Multiepitopic combinations of peptides, fusion proteins, and long lipopeptides also are at an early stage of clinical development, either alone or in prime-boost combinations with live vector-based recombinant vaccines. Some of these candidate vaccines will be tested as therapeutic vaccines in patients as a complement to antiretroviral therapy. tat has been shown to act as a viral toxin and to promote apoptosis of uninfected bystander T-cells and secretion of Th2 cytokines.

The population-wide effects of partially effective vaccines that do not prevent infection but only can reduce viral loads are largely unknown. Mathematical models predict that the factor with the greatest impact on reducing infections and deaths will be the degree of viral load reduction. A 90% reduction in viral load, which is a reasonable expectation with current candidate vaccines under development, would significantly reduce HIV mortality within 20 years after introduction of the vaccine.

The development of a safe, effective, and affordable HIV vaccine remains a formidable scientific and public health challenge at the dawn of this century.

## Conclusion

STIs remain an important and costly public health problem worldwide. Owing to the serious morbidity and sequelae, priorities for vaccine development should be focused on gonorrhea, chlamydia, and syphilis. However, there has been relatively little progress particularly with vaccine development for gonorrhea and syphilis, and significantly more work is required in chlamydia vaccine development. The problem of stimulating long-term immunity in the genital tract is still a challenge as little is known about genital tract immunology. Vaccination against STIs is one component of an effective STI/HIV prevention program. Focus on STI screening, treatment and behavioral change to reduce the risk of HIV transmission remain key components of an effective response. Work should continue in the search for effective vaccines against other STIs of public health significance.

## Introduction

There is no vaccine for HIV. Developing a safe and effective HIV vaccine is one of the defining scientific challenges of our times. Two (*gp120* proteins and adenovirus vector trials) approaches tested so far in large-scale human efficacy trials have failed and a third (canarypox vector plus *gp120* protein) showed only marginal efficacy. Novel vaccine approaches are currently in preclinical and early stage clinical trials, although there is no consensus on what an eventually successful approach will comprise. Although the challenges in developing an HIV vaccine are daunting, the global research effort surrounding HIV vaccine development is intense. This chapter examines (*i*) why HIV is such a difficult vaccine target, (*ii*) what immune responses may be helpful in protecting against HIV, (*iii*) the results of efficacy HIV vaccine trials to date, (*iv*) novel approaches in the pipeline, and (*v*) logistical issues surrounding the development of an HIV vaccine.

## Roadblocks to HIV Vaccine Development

### HIV STRAIN VARIABILITY

There are an enormous number of HIV variants, dwarfing issues of strain variability in other pathogens such as influenza. The substantial rate of viral replication, a highly error prone reverse transcriptase and significant rates of recombination between variants combine to generate a vast number of strains, even within a single individual.<sup>1,2</sup> This variation is compounded by the capacity of individual proteins to tolerate changes at numerous amino acid positions and retain still function.<sup>3,4</sup> Although most mutations result in defective virions, sufficient numbers of functional variants are generated capable of evading the gamut of humoral and cellular immune responses generated in each individual. The potential for new viral variants is highest during the acute phase of the infection when the availability of host cells, predominantly memory CD4 T cells, is highest. At a population level, this interplay between viral diversity and the host cell response manifests in the extensive sequence variation observed in the two most immunogenic proteins, *Env* and *Gag*, with 35% and 25% variation across subtypes, respectively.

How can a vaccine contend with such sequence variation? Many approaches utilize representative strains, those from an ancestral progenitor, or from “consensus” sequences that include the most common amino acid at each position. In either case, the intention is to include the best possible fit to the range of circulating sequences. In this scenario a vaccine sequence covering subtype C (the most common HIV subtype worldwide) will vary from circulating strains by a maximum of 8% for the most variable proteins, compared to the 20% variation that exists within the subtype.<sup>5</sup> Extending this principle to a group M vaccine, designed to cover all subtypes and circulating recombinant forms, variation from the vaccine sequence increases to 15%. An alternative approach is to rationalize antigen selection since responses to some HIV proteins are more effective than others.<sup>6</sup> Highly variable regions, such as Envelope are subject to escape with little cost to the virus and therefore are ineffective.<sup>7</sup> In comparison, structurally or functionally constrained proteins, such as *Gag* p24, are more conserved and escape, when it occurs, is often associated with impaired viral replication and reduced viral load.<sup>8–10</sup> However, it may be necessary to include additional less conserved sequences in vaccine antigens to maximize the breadth of the response.<sup>11–13</sup> The net effectiveness of vaccines that target sufficiently broad numbers of conserved HIV epitopes across the target population remains speculative.

### NEUTRALIZING ANTIBODY PROBLEM

Successful viral vaccines typically induce neutralizing antibody (NAb) that block most viral variants, but all current HIV vaccine candidates have failed to induce broadly reactive NAb. Monomeric *gp120* subunit vaccines induced antibody but were unable to neutralize HIV-1.<sup>14</sup> In HIV-infected individuals, NAbs are eventually produced but (*i*) typically only neutralize closely related strains and (*ii*) are soon rendered ineffective as a result of viral escape.<sup>15,16</sup> Inducing NAbs with broad reactivity to multiple strains is difficult for several reasons: (*i*) conserved epitopes in *Env* that are involved in binding to CD4 and the chemokine co-receptor are shielded by extensive glycosylation, (*ii*) the CD4 binding site is recessed and difficult to access by antibodies, and (*iii*) conserved

epitopes are exposed only briefly during conformational changes just prior to fusion with the host cell membrane. However, a limited number of broadly neutralizing antibodies have been identified in HIV-infected individuals and current vaccine development is focused on presenting these rare, neutralization epitopes.<sup>17</sup> Recent evidence does, however, suggest that low titer NAb can prevent exposure to low doses of simian and human immunodeficiency virus (SHIV) inoculation in macaques.<sup>18</sup>

### INTEGRATION AND LATENCY

HIV is a retrovirus and undergoes proviral integration into the host genome during the replication cycle. A proportion of HIV-infected cells, predominantly CD4 memory T cells, will become quiescent and harbor latent virus. Within these latently infected cells, virus production is absent and the HIV is effectively hidden from immune surveillance. A vaccine must therefore maintain sufficient circulating antibody to completely prevent infection or, in combination with cellular immune responses, limit infection to a small number of cells that can be destroyed. Failure to eliminate early infection will lead to an integrated viral reservoir and an established infection. Immune responses that target infected cells (such as CD8+ cytotoxic T cells) could still blunt the level of established infection leading to a delay in progression to AIDS; this has been observed in macaque-SIV studies and has now become a well-described secondary goal of HIV vaccines focussed on cellular immunity.

### LACK OF ROBUST SMALL ANIMAL MODEL

Attempts to develop robust rodent models of HIV that would allow ready investigation in simple animal facilities by many researchers have been marginally successful to date. Preclinical testing of vaccines is generally performed in nonhuman primate (NHP) models. Several species of Asian macaques have been shown to be susceptible to AIDS induced by simian immunodeficiency virus (SIV), a lentivirus closely related to HIV-1. A number of SIVs and chimeric SIV/HIV viruses have been used in various combinations to test vaccine prototypes. This is not an ideal situation for comparative evaluation of vaccine prototypes but will not be resolved until one model is validated by successful clinical trial evaluation. However, it is generally accepted that challenge with SIVmac239/251 or similar biological isolates best model HIV-1 infection. The models are also being fine tuned with regard to genetic predisposition to resistance, so that for example, MHC molecules that confer increased resistance to infection (e.g., Mamu-A\*01, Mamu-B\*17, Mane-A\*10) are controlled for in macaque studies. Certainly, which model is used for preclinical studies can demonstrably influence the outcome of a study and have implications for clinical development. This was highlighted in preclinical testing of the Merck Recombinant Ad5 vaccine, recently evaluated in a phase IIb proof of concept "STEP" trial. In preclinical testing, protection in rhesus macaques was demonstrated against the chimeric SHIV89.6P virus (which uses CXCR4 as an entry coreceptor and is more readily neutralized) but not against SIVmac239 (which uses CCR5 and is difficult to neutralize). In this case, clinical evaluation was better predicted by the SIVmac challenge.

### MUCOSAL IMMUNITY

Vaccines for HIV must also act at sites of HIV entry and early replication. HIV infections are most commonly transmitted via genital epithelia, and the acute phase of infection occurs primarily in the intestinal mucosa. Vaccines administered via a mucosal route (e.g., intranasal) typically induce responses at genital mucosal sites. Successful responses induced by HIV vaccines will likely need to be activated very quickly (within hours to days) at the site of entry to limit and potentially clear the virus at the initial site of infection.<sup>19,20</sup> The most effective vaccines tested to date in macaques are live attenuated SIV strains that in many cases are capable of controlling viral replication to below the level of detection. This protection is in part mediated by CD8 T cells acting quickly at mucosal sites.<sup>21,22</sup>

### ABSENCE OF NATURAL IMMUNITY

Correlates of protection are generally modeled on natural restorative infection but for HIV there is no precedent for successful natural clearance. The best response that we can model for vaccination purposes are responses induced in subjects with HIV that naturally control virus to very low levels for long periods; so called long-term nonprogressors. However, several genetic factors appear to be important in this select group of individuals<sup>23</sup> and it is difficult to draw conclusive findings that will be directly relevant for vaccine control in the wider community.

Taken together, these obstacles are unprecedented and present a novel challenge to vaccinologists. Several of the obstacles are illustrated in Figure 16.1. An HIV vaccine that induces sterilizing

**Fig. 16.1:** Obstacles to HIV vaccine research. Several of the many viral and host factors that limit the generation of effective immunity to HIV are illustrated during the HIV life cycle of infecting a susceptible target cell.

immunity may not be possible in the short term. However, a partially effective vaccine that reduces viral load to below 1500 copies/mL of plasma will curtail sexual transmissibility of the virus and substantially slow progression towards disease in vaccine recipients.<sup>24,25</sup>

## Immune Correlates of Protective Immunity

A successful vaccine for HIV needs to safely and effectively establish durable and protective immunological memory to prevent infection and/or disease. The majority of successful vaccines have relied upon an empirical approach however as discussed above, the exceptional challenge of HIV vaccination has meant that such strategies have been unsuccessful. It is now widely recognized that new insights into protective immunity and a better understanding of the immune events that occur during HIV infection are required to drive advances in vaccine design.<sup>26</sup> Analyses of both human studies and NHP trials are dissecting immune correlates of protection and have obtained a better understanding of immune events during HIV infection. Several key differences in the immune responses of those who demonstrate some control over viral replication have been identified and will hopefully assist future HIV vaccine design.

### ANTIBODIES

NABs represent key immune correlates of sterilizing immunity for most traditional vaccines. Passive transfer of high titer broadly neutralizing NABs confers protection from SIV/SHIV in NHPs<sup>27</sup> and partially delays the recurrence of viremia in HIV-infected subjects taken off antiretroviral treatment.<sup>28</sup> Thus far, vaccination attempts have not led to the induction of broadly reactive NABs and hence their use at preventing infection is frustratingly limited. Broadly, cross-reactive NABs have been found to arise during chronic infection and periods of high plasma viral loads and, although generally present in low titers, may play a role in partially controlling viremia. However, the effects of NABs are generally limited due to the rapid ability of the *Env* protein to mutate.<sup>29</sup> Findings from the passive transfer of NABs have also indicated the importance of the Fc portion of the antibody<sup>30</sup> suggesting that not only is the neutralizing ability of the antibody important but also the effector function. Antibody effector functions mobilize other cells of the immune system to result in the phagocytosis of antibody-coated virions and the destruction of virally infected cells though antibody-dependent cellular cytotoxicity (ADCC). Indeed ADCC activity against SIV infection induced by vaccination of rhesus macaques has been shown to correlate to control of infection.<sup>31</sup>

### CYTOTOXIC T CELLS

Cytotoxic T lymphocytes (CTL) cannot completely prevent infection but do play a crucial role in controlling HIV replication. The emergence of this response corresponds with initial control of primary viremia as well as being critical in determining the

set point viral load that dictates subsequent disease progression. Depletion of these T cells leads to loss of viral control in SIV and rapid disease progression.<sup>32</sup> CTL escape mutants of HIV are continually selected and are temporally associated with loss of immune control of infection. Why some CTL responses are more effective at controlling virus replication than others is currently being explored. It is now clearer that the “quality” of the T cells (their capacity to accomplish many antiviral functions) is important in achieving control of viral replication. High quality CTL are highly cytolytic and capable of secreting numerous cytokines and chemokines (such as IFN $\gamma$ , TNF $\alpha$ , MIP-1 $\beta$ ) and display good proliferative ability.<sup>33,34</sup> There is also evidence that T cell receptor avidity and the differentiation status of the T cells is important. Indeed, inducing and maintaining “effector” CD8 T cells may decrease the incidence of SIV acquisition of monkeys.<sup>35</sup>

### CD4 T HELPER CELLS

CD4 T lymphocytes orchestrate immune responses and are hence regarded as “helper” cells. HIV-specific CD4 T helper cells have been associated with transient control of viremia during early primary infection after interruption of antiretroviral treatment.<sup>36</sup> However, CD4 T cells are also a target cell for HIV infection, and the subsequent loss of CD4 T cells impairs the CD8 cytolytic T cell response.<sup>37,38</sup> Mechanisms to retain HIV-specific CD4 T cells early in infection are likely to contribute to the control of disease progression.

### HOST FACTORS

Numerous genetic factors have been demonstrated to correlate with different disease outcomes in HIV infection. The HLA type of an individual can have a profound effect on the course of disease. For example, HLA-B57 and HLA-B27 are associated with HIV control whereas HLA-B35, 45, and 53 are associated with HIV susceptibility.<sup>23</sup> Favorable MHC molecules present conserved viral epitopes to CTLs. Killer cell immunoglobulin like receptors (KIR) are expressed on natural killer cells and one KIR (KIR3DS1, which interacts with a particular HLA allele) is associated with HIV exposed but uninfected subjects.<sup>39</sup> Ways to manipulate these genetic factors for improved vaccine design are currently being explored.

It is imperative to establish immune correlates to facilitate and interpret future clinical trials. However, immune correlates may only emerge in the context of successful vaccine efficacy studies in humans. Reliable and robust assays to measure immune responses must be in place to enable dissection of immune correlates. There may be interactions between apparently effective immune responses that make dissecting the precise correlates of protective immunity difficult. In particular, correlates of protection involved in preventing disease progression during natural infection with HIV may not reflect those that would be protective in the presence of pre-existing vaccine induced immunity. These are substantial research issues for the coming decade.

## Failed Efficacy Trials of HIV Vaccines

Three HIV vaccine strategies have reached human trials where the efficacy of the vaccine is evaluated in large numbers of HIV-uninfected subjects at high risk of infection. Two strategies have been reported and one is ongoing. Both reported strategies showed no reduction in rates of HIV infection, although many important lessons were learnt for future studies.

### GP120 PROTEIN TRIALS

The two VaxGen trials assessed a series of vaccinations with recombinant HIV-1 Envelope *gp120* proteins in an alum adjuvant. This was an approach to induce neutralizing antibodies, based in part upon the highly successful hepatitis B surface protein vaccines. The first trial was initiated in North America in 5403 people, primarily at risk of HIV through male-to-male sexual activity. An overlapping trial was initiated in Thailand, involving 2546 people, primarily at risk of HIV through injecting drug use.<sup>40</sup> These huge trials were conducted successfully,<sup>41</sup> paving the way for future large-scale trials of biomedical prevention strategies.

No efficacy in either study was demonstrated; for example, in the Thai study there were 106 new HIV infections in the vaccine group and 105 new infections in the placebo group (Table 16.1). The lack of efficacy was interpreted as insufficiently broad neutralizing antibodies induced by the protein vaccination.<sup>42,43</sup> Earlier studies *in vitro* and *in vivo* in chimps showed some induction

of neutralizing antibodies, but these responses were subsequently shown to be limited primarily to lab-adapted strains of HIV. When the antibodies were tested against “primary” isolates of HIV-1 (i.e., not cultured in the laboratory and expected to be encountered in real-world), no effect on inhibiting HIV infection was apparent. This lack of induction of neutralizing antibodies capable of broadly inhibiting primary HIV-1 isolates still haunts the field today.

### VIRAL VECTOR TRIALS

Disappointing results with inducing neutralizing antibodies have led to a rethinking of HIV vaccine strategies. Many studies are now focusing more carefully on T cell immunity to HIV, since T cell immunity is linked to control of virus replication. Recombinant viral vectors, where HIV genes are expressed from within other viruses, are frequently used to induce T cell immunity since the expression of foreign antigen within infected cells leads to more efficient presentation to CD8 T cells. Several types of attenuated poxvirus vectors have been used, with variable success in inducing T cell immunity. One of these, an avian poxvirus termed canarypox, has proceeded into a human efficacy trial in Thailand.<sup>44</sup> This large phase III trial involves priming the immune response with a canarypox that expresses multiple HIV antigens and then boosting antibody responses with the *gp120* protein vaccines used in the VaxGen trials. 16,402 volunteers participated in the trial, which opened in 2003. Half of the volunteers received the vaccine (RV144:ALVAC+AIDSVAX) and half placebos; all were counseled on HIV prevention. Of the 8198 people injected with the placebo, 74 contracted HIV; of the 8197 who got the vaccine, 51 got the virus—a 31.2% reduction in infection ( $p = 0.04$  in primary analysis).<sup>45</sup> Further studies are now planned to tease out potential immune correlates of the protection observed and expand upon these findings.

A second generation of viral vector vaccines used replication incompetent adenovirus vectors. Phase I/II human trials showed these vectors were more efficient at inducing T cell immunity compared to most previous poxvirus vaccine trials. The first efficacy trial of this approach (the “STEP” trial, conducted primarily in North America) was terminated in late 2007 when no efficacy was observed.<sup>46</sup> A second efficacy trial of the same approach (the “Phambili” trial in South Africa) was in the process of enrolling subjects when results of the STEP trial were announced and this trial was also discontinued. Subgroup analyses of the STEP trial showed modestly increased rates of infection in vaccine recipients with prior adenovirus immunity or who were not circumcised. Being uncircumcised is a clear risk factor for HIV acquisition.<sup>47</sup> Earlier monkey-SIV studies had showed some efficacy of this adenovirus vaccine approach, particularly for reducing virus levels after infection.<sup>48</sup> However, efficacy was improved with this approach if prior priming of the immune system with a DNA-based vaccine was used (a so-called “prime-boost” T cell immunity approach shown to be highly immunogenic in monkeys<sup>49</sup>). A smaller efficacy trial has now started based on a multicomponent DNA

**Table 16.1:** Human Efficacy Trials on HIV Vaccines

Efficacy trial (reference)	Vaccine	Number of subjects	HIV infection rate vaccine	HIV infection rate placebo
VaxGen - North America {Flynn, 2005 #6380}	<i>gp120</i> proteins: 2 B clade proteins	5403	6.7%	7.0%
VaxGen - Thailand {Pitisuttithum, 2006 #6008}	<i>gp120</i> proteins: B clade and A/E clade	2546	8.4%	8.3%
Merck - STEP trial (HVTN 502) {Buchbinder, 2008 #6247}	Adenovirus type 5 vector expressing Gag, Pol, Nef	3000	3.2%*	2.8%*
Canarypox prime/ <i>gp120</i> boost	Canarypox vector expressing HIV antigens followed by <i>gp120</i> protein boost	~16,000	0.19%	0.28%
VRC/ HVTN505	DNA prime/ adenovirus type 5 boost	~1350	Trial ongoing	Trial ongoing

\* Primary endpoint rates were in those without prior adenovirus immunity.

prime/adenovirus boost vaccine.<sup>50,51</sup> Given the uncertainty surrounding the predictions of efficacy of HIV vaccines and the costs associated with such massive field trials, there is now a move towards smaller efficacy trials to show some benefit (so-called “test of concept”, or phase IIb trials) before larger, licensing trials (phase III trials) are undertaken.

## Vaccine Strategies in Preclinical/Early Phase Clinical Trials

### TRADITIONAL APPROACHES

Simple protein and whole inactivated virus vaccines are not protective in macaques. Live attenuated SIV viruses containing deletions in the Nef protein are, however, highly protective in macaques against a high-dose intravenous challenge with pathogenic SIV,<sup>52</sup> and to a lesser extent against heterologous SIV challenge viruses. However, such live SIV attenuated vaccines can eventually cause AIDS in a proportion of infant and adult macaques.<sup>53</sup> Further, humans with naturally acquired Nef-deleted variants can also eventually progress to AIDS.<sup>54</sup> More highly attenuated strains are unfortunately less protective in macaques. Efforts to produce “conditionally replicative” attenuated HIV strains are ongoing,<sup>55</sup> although it is unlikely that a live attenuated vaccine for HIV will proceed to human trials in the foreseeable future.

### INCREMENTALLY IMPROVED VACCINE STRATEGIES

A variety of newer approaches are being attempted to improve the efficacy of traditional approaches. Over 18 human HIV vaccine trials involving over 2500 participants have been completed since 2003 (see [www.iavi.org](http://www.iavi.org) and [www.hvti.org](http://www.hvti.org) for recent and current approaches). Currently, the HIV Vaccine Trials Network lists ongoing HIV human vaccine trials involving approximately 4500 participants. Many current approaches involve adenovirus based and/or DNA plasmid vaccines expressing a range of HIV proteins primarily aimed at stimulating T cell immunity.

Common themes amongst recent and ongoing trials, shown in Table 16.2, include (i) DNA delivery of antigens, (ii) DNA vaccine prime followed by a boost with various recombinant viral, plant, and bacterial vectors, (iii) augmentation of immune responses using novel adjuvants and/or cytokines, and (iv) the development of improved delivery systems to enhance immunogenicity (e.g., vaccines guns, virus-like-particles). DNA vaccines have generally been weakly immunogenic in humans, although electroporation of the DNA into the skin and the use of cytokines such as IL-15 have substantially improved their immunogenicity.<sup>56,57</sup> DNA prime/poxvirus boost regimens have been assessed in several phase I/II trials with mixed results. Phase II studies from an Oxford group using a DNA prime/attenuated vaccinia virus boost approach showed disappointing immunogenicity<sup>58</sup> although related trials are ongoing.<sup>35,56,59–73</sup>

**Table 16.2:** Selection of Newer HIV Vaccine Concepts<sup>35,56,59–73</sup>

Effector mechanism	Concept	Comment (reference*)
T-cell	<u>Improved vectors/antigens</u>	
	Modified vaccinia vectors	Modified to reduce expression of irrelevant antigens <sup>60</sup>
	Simian CMV	CD8-independent effector memory T-cells <sup>35</sup>
	<u>Multiple epitope vaccines</u>	
	Universal T-cell vaccine	DNA “Polytope” of over 200 CD8 epitopes <sup>61</sup>
	Polytope “coldspot” vaccine	Targets recombination “coldspots” within HIV <sup>62</sup>
	<u>Mucosal administration routes</u>	
	Nasal/vaginal/aerosol delivery	Increased mucosal response <sup>63–65</sup>
	<u>Augmentation of responses</u>	
	Electroporative delivery	Enhanced delivery of DNA to cells <sup>66</sup>
	Cytokine co-expression (e.g., IL-15)	Boosting T cell immunity <sup>56</sup>
	Nanoparticles	Protects antigen delivery to dendritic cells <sup>67</sup>
	<u>Novel host target</u>	
Neutralizing antibody	LINE-specific T-cells	Targets HIV-induced cellular proteins rather HIV itself <sup>68</sup>
	Reverse immunization	DNA construct to express mAb <sup>59</sup>
	Immune complexes	Antibodies complexed to gp120 with adjuvant <sup>69</sup>
	Self replicating alphavirus/HIV chimera	Replication stops when immunity neutralizes vaccine <sup>70</sup>
NK cell	Anti-lipid antibodies	Target cardiolipin on host monocytes to block infection <sup>71</sup>
	NK killing mediated by ADCC	Utilizes NK cells from innate immunity <sup>72</sup>

\*Adapted from a review of the HIV Vaccine Conference in 2008.<sup>73</sup>

## INNOVATIVE VACCINE STRATEGIES

There is a sense among HIV vaccine researchers that lateral thinking towards untried vaccine concepts may be required to induce effective immunity.<sup>26</sup> Scientific endeavor is in part shifting towards novel forms of vaccination that induce different types of immune responses. Some of the novel (and largely untried) concepts currently being evaluated are also summarized in Table 16.2 and include: (i) non-protein targets such as cardiolipin and other lipids, (ii) utilizing other arms of the immune system such as antigen presenting cells, NK cells and neutrophils, (iii) reverse immunization by the expression of antibodies from within persistent vectors,<sup>59</sup> (iv) targeting immunity against host cellular proteins required for HIV replication, (v) using gene therapies to enhance host immunity, (vi) using vectors with prolonged expression that stimulate durable immunity,<sup>35</sup> and (vii) self-replicating viral vectors that partially mimic the genetic diversity seen in natural infection. Many of these concepts have serious logistic and safety concerns, but hopefully they will identify key elements of protective immunity so that safer and simpler vaccines can then be designed.

## Logistic Issues Surrounding Availability of HIV Vaccines

If and when an HIV vaccine becomes available, delivering such a vaccine to those most at risk poses significant additional hurdles. First, the vaccine must be safe and acceptable to regulatory authorities. Many current HIV vaccines involve vectors or formulations that are untested in large numbers of people. There may be additional safety requirements for such novel vaccine designs. Second, the scale-up of manufacture required to deliver large numbers of doses globally is a significant hurdle. Many new vaccine types have not undergone successful scale-up of manufacture and new plants and processes may need to be developed, which could be both time-consuming and expensive. Third, delivering a vaccine to at-risk groups will be very challenging. Vaccine research and development is expensive and usually conducted by for-profit pharmaceutical agencies. As such, the resulting new vaccine is typically expensive, at several hundred US dollars per dose, and therefore unaffordable by many countries for widespread use. A pricing and payment structure will need to be put in place or vaccine delivery will be further slowed. Fourth, early generation HIV vaccines may not be fully effective, and how a partially effective HIV vaccine will impact on the epidemic is unclear. One problem with partially effective vaccines is that, once available, proving that another vaccine is more effective usually requires massively large clinical trials. Further, if the effect of the vaccine is short-lived, repeated vaccinations may be necessary to sustain reduced rates of transmission. This may be a particular problem with many vector-based vaccines since development of immunity to the vector limits the utility of revaccination.

## Conclusions

This chapter outlines many challenges surrounding the development of a safe and effective HIV vaccine. No HIV vaccine exists and recent failures of efficacy trials do not inspire great hope that an HIV vaccine will be available (and deployed) in the foreseeable future. Nonetheless, the intense global research effort, the improved understanding of factors that can partially control HIV infection, and the pipeline of highly novel vaccine approaches suggest that there is room for cautious hope that a vaccine will eventually be forthcoming.

### Summary

- There is no vaccine yet for HIV.
- There are many obstacles to developing a safe and effective HIV vaccine.
- The type of immunity required to control HIV is unclear, although both antibodies and T cell immunity can assist control of HIV.
- Three completed efficacy trials of HIV vaccine in humans failed to demonstrate protection; one completed trial showed modest efficacy and one trial is ongoing.
- Many HIV vaccine approaches are being tested in preclinical models and small human trials, with a renewed focus on developing innovative approaches.

## Partner Notification for Sexually Transmitted Diseases

Matthew Hogben • Rachel Kachur •  
Molly Dowling • Lauren Green

### Introduction

Partner notification for sexually transmitted infections and diseases (for convenience, we will abbreviate as STDs) is not a controversial concept with respect to infection control or patient care. Infected patients, their sex partners (infected or not), healthcare providers, and public health agents typically agree that partners of infected persons should be informed of their exposure and referred for evaluation and treatment.<sup>1–4</sup> Moreover, the mechanics of notification are theoretically uncomplicated. In the United States, for example, a palm-sized referral card can contain comprehensive instructions for an appropriate remedy tailored to local conditions in just about any jurisdiction in the country. Finally, in considering phases of an epidemic,<sup>5</sup> partner notification is an intervention suitable for all phases.

Data, however, are hardly consonant with the smooth progress of partner notification. Although many patients and partners hypothetically agree with in-person notification, studies with estimates of the proportion of partners who get either notified or treated suggest fewer than half of sex partners are notified of infection and seek evaluation.<sup>6–9</sup> These studies are typically of patient referral for gonorrhea or chlamydial infection. Public health staff are generally insufficient to cover the range of infections: in the United States; most people with primary or secondary syphilis are interviewed, but a distinct minority of people with any other bacterial infection receive similar services.<sup>10</sup> From another perspective, too few clinic attendees identify themselves as persons notified by either a sex partner or a trained public health professional to believe that partner notification works as well as one would hope. Direct documentation is hard to find, but one paper found fewer than 20% of syphilis cases detected in a US setting were due to partner notification.<sup>11</sup>

These problems are well-known, and, fortunately, many people have responded with various innovations. Such innovations, some in the guise of formal interventions, others in the form of programmatic changes, form the last of three parts in this chapter. This discussion includes efficacy, but also the transition to effectiveness and issues of appropriate coverage and scale for population-level prevention impact.<sup>12,13</sup> As these efforts are more meaningful when described in

context, we describe the role of partner notification in patient care and infection control in the first part of this chapter. In the second part, we include some of the history of partner notification, and its present status in different parts of the world and for different STDs. Finally, we have incorporated the role of partner notification in HIV infection into this chapter: HIV has been historically a special case, at least in the United States, and we discuss this history and more current efforts to integrate partner notification services for HIV with those for other STDs.

### Part I: Overview

#### RATIONALE FOR PARTNER NOTIFICATION

Partner notification serves individual-level, dyad-level, and population-level functions in healthcare provision. These functions are visible in the classic equation for infectious diseases,  $R_0 = \beta \times c \times D$ <sup>14</sup>.  $\beta$  refers to the per encounter infectivity of a pathogen,  $c$  refers to the rate of encounters, and  $D$  refers to the duration of infection. For STD, this translates to the product of the per sex act risk of transmission, the rate of sex partner change, and the duration of the infectious period of a given STD. The product, indexed as  $R_0$ , the reproductive number, indicates at what rates a disease or infection will either spread, die out or remain stable.

By notifying partners and bringing them to care, infected patients (hereafter index patients, see Table 17.1) and those partners individually receive health benefits through reduced odds of being reinfected (patients) and reduced odds of remaining infected (partners). In terms of the basic equation, the partner has  $\beta$  or  $D$  reduced in his or her personal equation, and  $D$  is also reduced at the dyad-level. At the population level, the reduction of  $D$  through treatment of infected partners reduces  $R_0$ , at least slowing the rate of infection. We can therefore say that partner notification confers benefits at the patient, partner, and community or population level. Ancillary partner services such as behavioral counseling affect other parameters in the equation. For example, if patients and partners begin to use condoms until in a closed, uninfected dyad (or larger sexual network, for that

**Table 17.1:** Nomenclature: Infected Persons and the Agents and Objects of Partner Notification (PN)

Infected persons	Agents of notification	PN type	Partners of infected persons
<b>Index patient</b> Index case Original patient	Public health staff, known as: <b>Disease Intervention Specialists (DIS)</b> , Communicable Disease Investigators (CDI), Public Health Investigators (PHI)	<b>Provider referral</b>	<b>Partners</b> (sex or drug-using), contacts
	Index patients	<b>Patient referral</b> , self referral	
	Physicians, nurses, public health nurses (excluding those trained as DIS), other mid-level providers	<b>Third-party referral</b>	

Note: Boldface terms are used as default terminology in this chapter.

matter), they will reduce per act infectivity. This reduction in  $\beta$  should be demonstrable at the population level if the intervention is sufficiently potent and widely applied.

We do not mean to imply that solutions are easily reducible to, say, better coverage in partner notification services. For example, in the United States, the current flat rates of gonorrhea across the last few years suggest that  $R_0$  is close to 1.0. That and the relatively low population prevalence ( $< 1.0\%$ ) raise the prospect that minor improvements in interventions such as partner notification and other partner services might tip the balance toward lowered incidence and prevalence. However, the pronounced racial and other disparities in American gonorrhea rates in the face of existing interventions<sup>15</sup> (e.g., partner notification) point toward the need for different interventions and combinations of interventions.

### TYPOLOGY OF PARTNER NOTIFICATION

If the point of notification is to bring sex or needle-sharing partners who need care into a system that provides it, the medium

through which one accomplishes notification varies. At one level, we can consider the role of the person who becomes the medium of notification: a public health staff person, the index patient whose partners are to be notified, or perhaps even the healthcare provider (Table 17.1). The suitability of each of these actors for conducting partner notification is largely driven by the healthcare and social structures in which they operate. Some proportion of the research and evaluation literature covered below addresses the efficacy of trained public health staff as agents who interview patients. They interview index patients for identifying and locating information about partners and notify those partners, while protecting the confidentiality of the index patient (Table 17.2). Beyond notification and referral, this approach can be used to uncover detailed information about networks, for example, a cluster of men with drug-resistant strains of HIV in Washington state.<sup>16</sup> In the United States, these staff are most commonly known as Disease Intervention Specialists (DIS), and the most widespread description of their notification activities is called provider referral (other terms include DIS-

**Table 17.2:** Principal Partner Notification Activities, Measures, and Outcomes

Phase	Activities			Common measures	Population Effects ( $\beta$ cD terms)
	Provider referral	Patient referral	Hybrids		
Identifying partners (sex or drug using)	Interview index patient	Patient receives instructions to notify partners	Interview index patient	1. Total Number of partners 2. Number of partners per index patient = <b>Contact Index</b>	N/A
Notifying partners	Public health staff locate and notify partners	Patient locates and notifies partners	Patient notifies partners; provider follows up with patient to ensure notification or contacts partners not notified by patient	1. Proportion of partners notified 2. Number of partners notified per index patient = <b>Notification Index</b>	Potential behavioral change may reduce rate of exposure (c)
Treating partners	Curative treatment for some STDs; entry to care for HIV			1. Proportion of partners infected and treated Number of partners infected and treated per index patient = <b>Brought to Treatment Index</b>	Cure reduces duration of infection ( <b>D</b> ); other treatment may reduce infectivity ( $\beta$ )
Collateral intervention	Education, behavior modification interventions, or social service referrals; spontaneous behavior modification by patient/partners			Varies	Improved healthcare-seeking reduces duration of infection ( <b>D</b> ); behavior change may reduce rate of exposure (c)

assisted referral and health department referral). This term should not be mistaken for activities conducted by healthcare providers, which we will call third-party referral. If the patient is the medium of notification, which is common for many infections, the most typical term is patient referral (self referral is also widely used). For this chapter, we will use provider referral, patient referral, and third-party referral.

The situation is made more complicated by differences in structural approaches to partner notification. In the United States, a reference to patient referral typically means leaving the patient to get on with the job, with either a brief instruction or suggestion from a healthcare provider and possibly an information card to give to that partner. Anecdotally, organizations like community clinics sometimes refer to this process as partner notification; the same term a categorical STD clinic would only use for provider referral. In the United Kingdom, the patient often remains the medium of notification, but the surrounding structure is different: an interview with a health advisor and later follow-up by that advisor with the original patient, during which the patient will be asked about referral actions. In many cases, whether the referred partner has sought care can be checked through clinic records and matched to the index case. Program managers in each country are thus describing quite different scenarios when they speak of patient referral as an approach to STD control. We cover these issues in more detail in Part II.

## PARTNER NOTIFICATION ACROSS STDs AND POPULATIONS

### Infections and Diseases

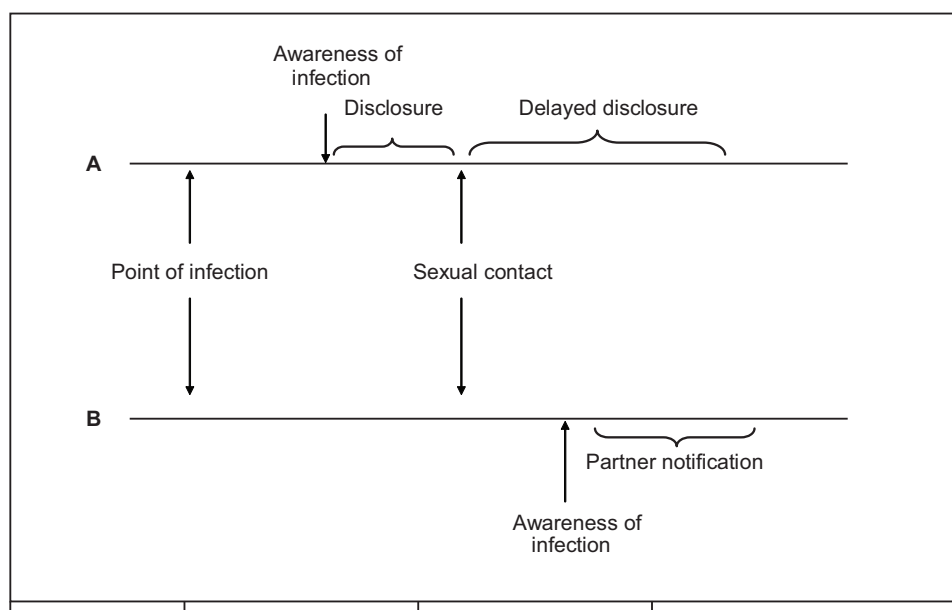

Many of the principles in provider, patient, and hybrid versions of partner notification apply across a range of STDs, including HIV. Nevertheless, differences among the effects of pathogens and differences among populations and sub-populations can change the odds of a given approach working or drive different approaches entirely. For example, the increase in the use of the internet for sexual partnerships in some countries may reduce the effectiveness of in-person provider referral, especially if the index patient has only an e-mail or screen name as identifying information. These conditions have also driven internet-mediated partner notification as a novel approach, both through DIS and patients.<sup>17,18</sup> Internet partner notification (IPN) is covered in more detail in Part III.

In the US and most other countries partner notification for chlamydial infection receives a lower priority than syphilis, HIV, or gonorrhea. Australian physicians routinely discuss partner notification for chlamydia-infected patients, but less than half provide referral cards, and most would find more resources useful.<sup>19</sup> In a 2001 survey of US health departments, composite statistics revealed 89% of syphilis patients, 52% of HIV patients, but only 17% of gonorrhea patients and 12% of chlamydia patients received any public health intervention such as an interview, a precursor to provider referral.<sup>10</sup> We have usually used these statistics to illustrate how the burden of STDs precludes

provider referral for all, but they also serve as a rough national prioritization. Compared to other countries, the US may be especially attuned to syphilis control, given the higher prevalence and particular historical circumstances. Nevertheless, whether syphilis serves as a reminder of past and continuing inequities<sup>20,21</sup> or as a sentinel event in countries with very low rates, syphilis cases tend to receive more attention than most other STDs, curable or not.

In 2007, the Community Guide to Preventive Services recommended provider referral as a strategy for finding previously undiagnosed cases of HIV.<sup>22</sup> The accompanying review estimated that about 20% of persons tested through provider referral were previously undiagnosed HIV-positive cases, making the strategy a relatively efficient means of bringing people to care.<sup>23</sup> In countries with access to care, the role of partner notification is therefore an important component of infection control and can be integrated with behavioral interventions.<sup>24</sup> Moreover, as HIV-infected individuals as a group tend to reduce transmission risk behaviors once they know their status,<sup>25</sup> notification has substantial collateral benefits for infection control. Current recommendations in the US suggest public health involvement with HIV partner notification, including early initiation of the process for individuals, once diagnosed, and use of surveillance data to generate cases for partner services programs. These points certainly do not preclude patient referral for HIV, as many patients will notify partners. Data included in the Community Guide review did point to a similar number of new positives per person tested via patient referral as for provider referral (there was an insufficient *quantity* of data to recommend the strategy). In the US, cost-effectiveness varies substantially, according to the prevention effectiveness as well as the level of fixed costs (e.g., DIS salaries). Figures generated in a recent review together with previous estimates, however, place almost all estimates at under US \$8000 per case detected (2007 dollars, with one outlier at \$22,000).<sup>26</sup> In developed economies, such figures are reasonable, considering value of entry to care and the prevention value of identifying people with HIV.

Discussions of partner notification sometimes include issues around disclosure, especially in the case of HIV (and some other viral infections). The most salient difference between partner notification and disclosure is the relationship between when a person becomes infected and when he or she actually knows he or she is infected. In Figure 17.1, Line A represents a continuum in which a person is infected and then aware of his or her infection *before* having sex with someone. Aware of his or her status, that person can now disclose infection status to the prospective: this is disclosure. Some researchers have observed that HIV status disclosure sometimes occurs after first sex with a new partner, but during the course of a relationship: this is delayed disclosure.<sup>27</sup> Line B in Figure 17.1 represents a continuum in which a person is infected and becomes aware of his or her infection after having sex with a partner. When that person uses some method of partner notification to make sure that partner is notified of exposure, he or she is using partner notification.

**Fig. 17.1:** Partner notification versus disclosure. Line A represents a continuum in which a person is infected and then aware of his or her infection prior to a new sexual contact. That person is in a position to disclose infection status to the contact, on a pre-contact (disclosure) or post-contact (delayed disclosure) basis. Line B represents a continuum in which a person is infected and becomes aware of his or her infection after a new sexual contact. Ensuring that contact is aware of his or her exposure constitutes partner notification. For curable infections and diseases, these distinctions become irrelevant for contacts that occur post-cure.

From the point of view of the partner, delayed disclosure and partner notification have some overlap. In both circumstances, people may switch between partner notification and disclosure situations for curable infections. That is, people perform partner notification for their sex partners prior to becoming aware of infection and disclosure for subsequent partners up to the point of cure. Thereafter, there is nothing to disclose. For those who become infected with HIV, however, there is no point of cure, and infected persons inexorably move into situations where disclosure is the relevant topic. This chapter is not the place to discuss Disclosure Research and other literature, but we note (a) HIV positivity disclosure is not a trivial undertaking for many people and (b) public health staff involved in HIV partner notification are dealing with people facing precisely that undertaking for the rest of their lives. The goals are the same, and much about HIV partner notification processes can be readily integrated with partner notification for other STDs (e.g., syphilis, gonorrhea, and chlamydial infection in the United States' 2008 recommendations),<sup>28</sup> but this is one important contextual difference that needs to be borne in mind for effective partner services.

Other viral infections are subject to the same parameters as HIV with respect to partner notification as a route to care rather than cure and in the matter of long-term behavioral change. Hepatitis C (HCV) partner notification efforts occur from time to time, typically in the context of a dense sexual or drug-using network, rather than as standard program practice. Likely, because investigation is rare and therefore undiscovered

infection is relatively prevalent, efforts can be rich in case-finding. A Dutch investigation of a man with acute HCV infection and rectal lymphogranuloma venereum (LGV) led to 16 other men, 7 of whom had been recently infected with HCV; 6 of these men had LGV proctitis and were seropositive for HIV.<sup>29</sup>

For herpes simplex virus (HSV) and human papillomavirus (HPV), partner notification, if it happens, will be almost exclusively via patient referral. For the patient, the balance of costs and benefits between notifying and not notifying partners differs by infection. HSV is responsible for morbidity *per se*, transmissible with or without symptoms, as well as being a known risk factor for HIV transmission.<sup>30,31</sup> Most authorities consider partner notification and disclosure generally helpful as a matter for patients and their partners, with physicians certainly advocating patient referral when they diagnose a patient.<sup>32</sup> Of course, this advice depends on a diagnosis, and many HSV cases remain either undiagnosed or not diagnosed until the patient has been infected for some time. In a recent Peruvian randomized, controlled trial (RCT), 25% of the sample were seropositive for HSV-2, but only 7% reported any ulcer symptoms (some of which were syphilis).<sup>33</sup> The value of partner notification as a means of population-level infection control is debatable without good data on what proportions of patients are diagnosed early after infection (i.e., before they have most likely transmitted the infection further). Information in this area is minimal.<sup>34</sup>

In contrast to the cases for HSV and HIV infections, HPV infection demonstrates a circumstance under which partner notification is *not* necessarily required. The rise in profile of HPV

stimulated a survey conducted for CDC in which physicians and mid-level providers (nurse practitioners, physician's assistants) were asked about various clinical preventive services and ancillary practices concerning HPV diagnosis.<sup>35</sup> Among the services were questions on partner notification practices of providers with their female patients diagnosed with HPV. In spite of the fact that partner notification for HPV has minimal theoretical impact (let alone empirically demonstrated impact) on population-level infection control and is of dubious value to male sex partners, analyses showed that over half of providers gave almost the identical patient referral instructions along the patient referral lines discussed above.<sup>36</sup> There is certainly no overarching reason why women should keep their infection status secret. Condom use may speed remission,<sup>37</sup> and, if (re)introduced into a long-term relationship, there will presumably be a discussion of why. The principal variables in the balance pertain to the woman's level of comfort discussing her infection, trust in her partner, and similar, patient-centered factors more relevant to disclosure than partner notification. Only if the relationship has ended or is likely to end is there a clear, partner-centered case for disclosing infection status.

## Populations

Priority populations vary according to local epidemiology and even societal norms and prejudices. In the US, CDC guidance on partner services does not set specific priorities, although people with repeat infections, acute cases of HIV (with potential for post-exposure prophylaxis with recent partners), or coinfections are typically prioritized highly in programs. Pregnant women or men whose sex partners are pregnant are also high priorities almost everywhere. The principal reason for the latter is, of course, the opportunity to reduce the rate of adverse outcomes of pregnancy attributable to STDs, but pregnancy is also a marker for unprotected sex. A New Zealand study of women presenting for abortion services found a 10% rate of STDs (8% chlamydial infection), demonstrating that women seeking these reproductive health services are also good candidates for testing and partner notification interventions.<sup>38</sup>

Domestic violence attributable to partner notification is assessed routinely by DIS, but less obviously so by providers giving advice to patients. Moreover, if index patients are the medium of notification, there is also the question of whether they will perpetrate violence. Complicating matters further is the endemic level of overt domestic violence in relationships. For example, one Kenyan cohort study looked at domestic violence as a predictor of vertical transmission intervention uptake among HIV-infected pregnant women.<sup>39</sup> Of 2836 women responding, 28% reported previous domestic violence. Although this was not statistically associated with decreased rates of partner notification (via patient referral), OR = 0.7, 95% CI = 0.5–1.1, women who were HIV seropositive were almost 5 times as likely to experience violence as those who were HIV seronegative, OR = 4.8, 95% CI = 1.4–16.0). Only 1% of women, however, actually reported violence

attributable to test results, and a South African study proactively assessing violence reported no adverse events from 106 women (10% of partners were “angry, embarrassed, or confused”).<sup>40</sup> A US study of Mexican American and African American women reported a high rate of physical or sexual abuse (63% lifetime), but this rate was not associated with partner notification.<sup>4</sup>

Although much partner notification research, especially its expansion into common STIs such as chlamydial infection, has centered around sex partners, one should not overlook its use in reaching needle-sharing partners in drug-related networks of infection. Such networks are sometimes characterized anecdotally as difficult and dangerous. But at least some evidence suggests that drug users are at least as cooperative as those with only sex partners. A Utah evaluation of HIV partner notification in which the two populations were explicitly compared found that 93% of drug users cooperated to the extent of naming partners, versus 76% of others (RR = 1.2, 95% CI = 1.1–1.3).<sup>42</sup> One might suspect these results were biased by confounds such as differential rates of gay men in the two groups. These data were collected between 1988 and 1990, at a point when the stigma attached to male homosexuality and HIV infection was still extremely high.<sup>43</sup> However, when controlling for this and other factors (e.g., age), the difference was still statistically significant. Utah HIV partner notification at the time was also a hybrid program in which index cases were interviewed, but chose patient referral versus provider referral. Across these notification methods, 74% of named partners were notified, with slightly higher rates among sex partners (75%) than needle-sharing partners (65%). Overall, the number of partners found per index case was highest among drug users (3.3), due to the larger number of partners named by drug users.

Finally, there is the question of partner notification for incarcerated persons, for migrants and for the homeless. In the US, people are sometimes screened for common STDs or HIV when being processed in the criminal justice system, and STDs such as syphilis are often concentrated in American jails.<sup>11,44</sup> Processing may simply be a matter of 24 hours in custody; if this is the case and test results are swift, the arraigned individual may receive patient referral instructions (whether he or she is in the mood to adhere to referral instructions is another matter). If test results lag by a period longer than the individual is in custody, then the infected patient may be informed of his or her status when contacted for, say, a court appearance, but the delay reduces the effectiveness of partner notification in infection control. Provider referral is possible and a more plausible means of notification if the individual is incarcerated for longer periods of time. One cost-effectiveness study in Massachusetts, US found that adding partner notification for female sex partners of male inmates resulted in no net costs (at the healthcare system level) when the benefits of detecting infection in partners was considered.<sup>45</sup>

Migrants and homeless populations are severely understudied with respect to implications for partner services. A 2007 study of HIV diagnoses in California found that immigrants (in this study, Hispanic) had delayed HIV diagnosis rates compared to

others, pointing to the need for integrated partner notification services across jurisdictions.<sup>46</sup> Interestingly, other than symptoms, the one factor in seeking testing was an STD/HIV diagnosis in a partner. The good news is that patient referral occurs among this population and drives testing. The bad news is that the evidence does not support the notion that the current rates of patient referral are enough. For those who migrate more frequently, complications include the potential for acquisition in one place, transmission in another, and diagnosis (if any) in a third place. Migrants, particularly if vulnerable to arrest and deportation, are at-risk for acquisition as well as a potential vector for transmission between populations (i.e., bridging).<sup>47</sup>

Many of these conditions around testing, treatment, and partner notification apply to the homeless as well. Some studies of contact tracing for tuberculosis among the homeless exist,<sup>48–50</sup> but STDs partner notification in this group is even less well-studied than migrants or the incarcerated. One Canadian study estimated homeless people in a shelter had an average of 97 contacts in any one day, rising to 120 over the course of a week.<sup>51</sup> The difficulties in tracking the index patients (let alone partners) after a week were substantial, as people tended to leave the shelter by 7 days. Although this paper was predicated on containing an airborne infectious disease (e.g., SARS, tuberculosis), the principle of patient transience and transient relationships still holds.

### Partner Notification Coverage and Scale

Ideally, all persons exposed to an index case would receive the most effective forms of partner notification. Often, this means provider referral or at least direct public health involvement in the notification and referral process. Resource constraints, however, mean that this relatively labor-intensive approach is cost-prohibitive for many programs. One then has to consider coverage issues: how many index cases must receive services in order to reduce future incidence and therefore exercise population-level STD control?

New York state data from the 1990s provide an example of such an exercise. Gonorrhea rates in New York state dropped substantially during the 1990s, as they did elsewhere in the United States, but analysts demonstrated that the proportion of index cases interviewed in a given year predicted incidence in the next year.<sup>52</sup> Specifically, a 10% increase in the number of partners treated (itself a function of the proportion of index cases interviewed by DIS) was associated with a 6% decline in gonorrhea rates. Collateral analyses put the necessary level of coverage, defined as proportion of gonorrhea index cases interviewed, to affect population prevalence at about 40% (with about 52% of partners medically evaluated and 30% administered prophylactic treatment). With respect to scope, New York also tested the effects of concentrating efforts in core areas, defined simply as areas of high prevalence, finding that core area approaches resulted in reduced subsequent prevalence compared to efforts to interview cases evenly across geographic areas.<sup>53</sup> Given the propensity for gonorrhea to be clustered geographically,<sup>54</sup> a core area approach on the grounds of scarce resources would seem to have wide merit.

Demonstrating that one can achieve sufficient coverage with one method to affect population STDs rates does not mean that only that method should be applied. A program's scope can include a minimum level of coverage of a method like provider referral and also include alternative methods for those not covered by provider referral. For example, New York's interview algorithms in public STDs clinics could cohabit with patient referral instructions, including referral cards and expedited partner therapy (EPT), with neither approach suffering because the other exists.<sup>55</sup> In the United States, the most recent recommendations for partner services suggest a variety of approaches tailored to local conditions, with the underlying premise that STDs program scope should consist of having some partner services protocol for HIV and several other STDs.<sup>28</sup> Sweden has addressed both scope and coverage of partner services for chlamydial infection through making physicians responsible for partner notification. That is, the coverage benchmark effectively became 100% of diagnosed cases, and scope of services included several provider and patient-mediated approaches, including patient referral instructions, physician-based notification and referral, and patient-delivered partner therapy (PDPT).<sup>56</sup> Ramstedt's evaluation of these approaches showed that each enhancement over no effort was associated with reduced reinfection rates (10% with no intervention, 8% with patient referral, 5% with physician referral, 2% with PDPT).

## Part II: History and Current Scope of Partner Notification

### PARTNER NOTIFICATION IN HISTORY

References to syphilis in Europe, including the knowledge that it was sexually transmitted, date back centuries,<sup>57</sup> and there remains something of a cottage industry in speculating about which monarchs, clerics, and other powerful figures were infected with syphilis before dying. Efforts to stem transmission, if any, were more attuned to isolating infected individuals during their symptomatic phases (if they were not too powerful to be thus bothered) and periodically pinning the blame for syphilis on prostitutes and other disfavored groups.<sup>58</sup>

No doubt some physicians asked their patients to tell their spouses of infection. In the absence of efficacious treatment, partner notification's role in stemming transmission relies on people eliminating or limiting the amount of sex they have, or at least avoiding new partners. Systematic efforts to have sex partners informed of their exposure date back to the early 20th century in Sweden, where partner notification became compulsory for syphilis and gonorrhea in 1918.<sup>59</sup> Both patients and physicians are legally responsible for notification; physicians can discharge their obligations by notifying a specified public health medical officer in writing.

In the United States, Thomas Parran, the Surgeon-General, took a different approach.<sup>60</sup> Parran conceived STD control as a public health concern, not as a moral imperative. By the end of

World War II, the US Public Health Service had trained a small cadre of (six!) professionals to interview syphilis patients about their sexual contacts and trace them—hence the term “contact tracing”—and refer them for treatment with penicillin.<sup>61</sup> This model with the DIS survives with relatively few modifications as a vital component of syphilis control today.

Most of the process and outcome indicators of partner notification activity identified in Iskrent and Kahn’s 1948 paper on the evaluation of syphilis control activities, such as the contact index, epidemiologic index and the brought to treatment index are still used as indices of provider referral success.<sup>62</sup> Other categories for the disposition of cases, for example, “out of jurisdiction,” are also those used currently. Only the lesion-to-lesion index (the number of primary or secondary cases found as a result of interviewing a primary or secondary case) is perhaps less widely used, although easily measurable. The lesion-to-lesion index is indicative of the speed as well as the success rate of provider referral for syphilis and, given the high value of detecting a case in primary or secondary stage (where most transmission takes place),<sup>11</sup> serves some role in measuring the effectiveness of a program in stemming transmission. Iskrent and Kahn cite an average of 0.14 (i.e., 14 primary and secondary cases found per 100 primary and secondary cases interviewed) around 1946; it is unlikely this rate would be exceeded today.

An advantage of method and measurement consistency is that comparisons across time have more meaning. Selecting here for a few investigations between the 1940s and the 1980s, we find investigations in Arkansas, US reporting a contact index of 3.26 for syphilis, with 324 infections found among 655 sex partners of 201 index patients.<sup>63</sup> Of those 324 infections, 167 (52%) were “brought to treatment,” the remainder were previously treated. A review of UK programs use the same data for the “Tyneside scheme;” here, the main infection is gonorrhea, there is some assessment of whether the contacts are same or opposite sex, and the contact index in 1970 is 1.35.<sup>64</sup> This review in particular covers 27 years of partner notification in northeast England and is one of the most comprehensive data-driven reviews in the field. The citation of 80% of contacts located and notified by public health staff in 1946 is close to US figures<sup>63</sup> and a reasonable benchmark for in-person provider referral for syphilis or gonorrhea today. Another 1972 review contains comparisons of STD rates across nations.<sup>65</sup> The resurgence of syphilis is noted, interestingly, the rates of resurgence ran higher in countries *without* established public health STD prevention (this is, of course an ecological comparison, and plausibly confounded with other social variables).

A 1977 RCT of patient referral with referral cards against provider referral suggested that the methods were equivalent.<sup>66</sup> The brought to treatment indices for previously undiagnosed infections in each RCT arm were almost identical, 0.25 for patient referral and 0.26 for provider referral, most seen within 2 weeks in both conditions. Results suggest clinic patients for whom follow-up is infeasible may not be harmed by patient referral,

but this was patient referral with some enhancements— referral cards and some time spent discussing the importance of partner notification. Later reviews suggest provider referral generally results in more cases seen.<sup>67</sup>

All the same, clinical situations often do not present a clear choice between provider referral and patient referral, nor is it clear there should be one. In Colorado, HIV patients in the 1980s discussed referral options with providers, arriving at a mutual decision.<sup>68</sup> Providers followed up on cases where patients had agreed to notify partners and vice versa. At one month, patients had notified 57% of the partners they had agreed to notify, and DIS had notified 85% of the partners they had attempted to contact. DIS following up with partners that patients did not notify brought the first total up to around 90%, and, interestingly, patients following up unsuccessful provider referral raised the second total also to around 90%. Although DIS clearly notified the majority of partners (80%), the larger point is that a program with early intervention (the interview), choice and a fallback option can do better than relying on a single strategy. For a similar perspective, a Swedish retrospective evaluation of various strategies showed how choice and informed discussion can strengthen partner notification for an infection as prevalent as chlamydia.<sup>56</sup> Swedish physicians could discharge their responsibilities in several ways at different time periods— third-party referral, contact slips, giving patients medications for partners, and each was associated with reduced index patient reinfection.

The Swedish experience with permitting patients to take medications to their partners during the 1980s is a reminder that what is thought of as innovation has often been tried before. On the publication of an RCT in 2005,<sup>69</sup> one of the authors (MH) received a letter from a physician in North Carolina. He referred us to a short paper he published in the *New England Journal of Medicine* in 1977.<sup>70</sup> The report referred to giving extra doses of medication for the “consorts” of women diagnosed with trichomoniasis. Among the 31 women who received extra doses, all who were tested were clear at an initial test of cure and 1 was subsequently found to be infected 10 months later. Two patients reported the partner refused to take medications, and those patients had no further sexual contact with either. The next piece of US research on the topic was published in 1998.<sup>71</sup>

## PARTNER NOTIFICATION TODAY: CURRENT SCOPE

The Community Guide for Preventive Services recommends provider referral for HIV,<sup>22</sup> and there are recent RCTs for innovative practices (see Part III). References for the effectiveness of provider referral for gonorrhea control often include a Colorado study in which the introduction of provider referral in a military setting resulted in a 20% decline in incidence among the civilians in the surrounding community.<sup>9</sup> There are, however, fewer reviews of the effectiveness of standard STD provider, other third party, and patient referral.

Brewer's 2005 review of case-finding effectiveness for syphilis, gonorrhea, chlamydia, and HIV identified brought-to-treatment indices of 0.22–0.25 for the first three STDs and 0.13 for HIV.<sup>72</sup> His review drew studies of program activities (mostly provider referral) between 1975 and 2004. This comprehensive review of program activities (mostly provider referral) serves as a baseline for our update. We searched the published literature between 2005 and February, 2009, searching for studies that described partner notification activities and linked them to outcomes. (The original version of this search produced evidence tables for the 2010 US STD Treatment Guidelines.)

We subsequently tabled 26 papers with partner notification interventions and outcomes. Many studies were easily categorized into the traditional provider-based (7 studies) and patient-based (11 studies) referral frames; these are in Tables 17.3 and 17.4 and form the database for estimating the current effectiveness of both forms of notification today. A further 8 studies are tabled separately to cover the UK audits of their partner notification system as a special evaluation of a national (i.e., population-level) control program.

### Provider Referral: Public Health Staff as the Medium of Notification and Referral

The 7 studies in Table 17.3 come from Sweden (2 studies) the US (5 studies) and include provider referral efforts for men and women, heterosexual men and MSM, diagnosed with syphilis, HIV, HBV, gonorrhea, or chlamydial infection.<sup>73–79</sup> Thirteen contact indices based on public health staff interviewing (median = 2.05) ranged from 0.5 for cases of acute HIV in San Francisco<sup>74</sup> to a substantial outlier, 6.8 for predominantly MSM diagnosed with syphilis across 8 US cities with reported outbreaks.<sup>77</sup> Seven of the 12 estimates fell between 1.0 and 3.0; there was no clear pattern by STD. Instead estimates tended to clump by study site; for example, the contact index of 0.80 for MSM diagnosed with syphilis in Georgia, US was closer to the 0.72 estimated for heterosexual syphilis-infected men in the same setting than almost any other estimate.<sup>75</sup> Although a contact index of <1.0 is often seen as an indicator of program failure, we shall see below (in *Program effectiveness*) that, if most contacts are notified and many are infected, provider referral based around low contact indices can indeed be useful.

**Table 17.3:** Provider Referral Partner Notification Studies Published Between 2005 and 2009

Citation/ quality	Study design	Population and setting	Exposure or intervention	Principal outcome measures	Principal findings	Miscellaneous design and analysis considerations
Sylvan & Hedlund 2009 <i>J Eur Acad Dermatol Venereol</i> <sup>73</sup>	Retrospective evaluation	Youth community based health offices Uppsala County Sweden. 463 cases CT (Female 299 and male 164)	Patient interviewed by sexual health advisor or physician	Number of: contacts, successfully contacted partners, and accuracy of the numbers reported for unsuccessful contacts	Contact index (female) = 2.21 (660/299). Contact index (male) = 2.36 (386/164). Successful partner notification 73%	Originally, 52% of female's partners and 20% of male's partners incorrectly recorded as unsuccessful partner notification
Ahrens et al. 2007 <i>JAIDS</i> <sup>74</sup>	Retrospective evaluation	763 HIV patients San Francisco 2004–2006	Patients interviewed for partners with HD follow-up offered	Patients interviewed, partners elicited and tested	79.6% (607/763) patients interviewed Contact index for acute cases = 0.5 (15/30); non-acute = 0.85 (339/398); long-standing = 1.65 (553/335) 13% of partners for acute and non-acute newly diagnosed with HIV NNTI = 25 (acute), 21 (non- acute), 39 (long-standing)	
Samoff et al. 2007 <i>Sex Transm Dis</i> <sup>75</sup>	Retrospective, record review	401 index male syphilis patients; MSM (243) or MSWO (158); Atlanta, GA	Health department staff interview patients for partners	Partners notified and tested	Contacts located for MSWO 90 (77%) and for MSM 159 (77%)	Almost identical case- finding, but a larger proportion of MSM partners not followed up
Gunn et al. 2006 <i>Sex Transm Dis</i> <sup>76</sup>	Prospective evaluation	190 reported cases of chronic HBV (aged 15–45) in high-morbidity communities, San Diego, CA 1999–2000	Patient interviewed for partners by public health staff, who follow- up with partners (partners within past 1 month)	Partners notified, beginning treatment, completing treatment	129/190 cases interviewed; 85 reported partners in past 1 month; 46 accepted PN services and named 47 partners; 38/47 partners were notified; 14/15 eligible began treatment (9 completed)	Treatment constituted a series of 3 vaccinations for HBV

Citation/ quality	Study design	Population and setting	Exposure or intervention	Principal outcome measures	Principal findings	Miscellaneous design and analysis considerations
Hogben et al. 2005 <i>Sex Transm Dis</i> <sup>77</sup>	Retrospective evaluation (aggregate of 8 cities)	1517 MSM patients with early syphilis, 8 US cities	Public health staff interview patients for partners and conduct follow-up	Partners notified, tested, cases found	Contact index = 6.8 (10,254/1517) Median notification index = 0.94 Median cases found per index case = 0.26 (includes previously treated), 0.09 (excludes previously treated)	Study is a review of PN in cities with syphilis outbreaks; contains evaluation data for 8 cities. Median proportion of all partners claimed who were notified = 14%
Brewer et al. 2005 <i>Sex Transm Dis</i> <sup>78</sup>	Randomized, controlled trial	123 STD clinic patients (syphilis, GC, CT) reporting multiple partners in past 3 months, Colorado Springs, CO 2000–2001	DIS interviews with mnemonic cues: 1. Individual characteristics 2. First names 3. Alphabetic, location, network, roles	Partners elicited, located and notified  Outcome data include the increment for each experimental condition and the final index for each condition	Incremental contact index per condition (final index): 1. 0.28 (2.73) 2. 0.29 (2.14) 3. 0.57 (2.80) Incremental notification index per condition (final index): 1. 0 (1.02) 2. 0.10 (1.12) 3. 0.12 (1.51) $P < 0.05$	56% (82/145) of partners across conditions were infected
Osterlund et al. 2005 <i>Int J STD AIDS</i> <sup>79</sup>	Prospective evaluation	676 persons diagnosed with CT (any setting) Varmland Co., Sweden 2001	Trained midwives conduct interviews and notify partners	Partners elicited, notified and treated	Contact index = 2.05 (1389/676) 73% (1017) of partners were tested; 62% of these were CT- positive and treated	Data are compared to 1999 data in which physicians conducted PN (contact index = 1.56, 67/43)

GC, gonorrhea; CT, Chlamydia; NNTI, number needed to interview (to find an infected case); MSWO, men who have sex with women; MSM, men who have sex with men.

**Table 17.4:** Patient Referral Partner Notification Studies Published Between 2005 and 2009

Citation/ Quality	Study design	Population and setting	Exposure or intervention	Outcome measures	Principal findings	Miscellaneous design and analysis considerations
Thurman et al. 2008 <i>Int J STD AIDS</i> <sup>81</sup>	Cross sectional analysis	166 pregnant females with STI San Antonio, TX	Interview within 1 month of diagnosis (treatment or retreatment provided as needed)	Reports of intent to notify partner, partner notification	136 had 1 partner; 30 with multiple partners. 88.2% with 1 partner notified partners versus 54.5% of those with multiple partners	3 variables predicts PN: steady relationship, 1 partner and recent activity
Harry & Sillis 2008 <i>Int J STD AIDS</i> <sup>82</sup>	Retrospective study	60 (17 female, 43 male) newly diagnosed HIV patients – Bure Clinic East Anglia (UK) 1997– 2004	Patients counseled, patients responsible for referring partners	Partners notified	Overall, 31/60 (51.7%) reported notifying partners. PN reported by 23/60 (38.5%) homosexuals 15/60 (25%) bisexuals and 34/60 (57.1%) of heterosexuals	Small cohort over a long period of time
Niccolai et al. 2008 <i>Prev Med</i> <sup>83</sup>	Survey	135 CT- positive women, Connecticut, USA 2005–2007	Prospects of patient referral: patient-reported intentions to notify partners	Proportion intending to notify (includes self-reported notification), correlates of intention	Patients reported 187 partners and intended to notify (or reported already notifying) 75% of them; Relationship length and perceived quality were associated with positive intentions in multivariate models	Other indicators of relationship nature and quality were associated with intentions in univariate analyses

Citation/ Quality	Study design	Population and setting	Exposure or intervention	Outcome measures	Principal findings	Miscellaneous design and analysis considerations
Bakken et al. 2008 <i>Scan J Infect Dis</i> <sup>84</sup>	Longitudinal case series study	81 CT positive men identified in another cross- sectional study; 2005	Participants interviewed on PN intentions at tx visit and on PN actions at the test-of-cure visit; questioned about sex partners during the last 6 months	Partners notified and treated	65 interviewed at tx visit reported they intended to notify 100/165 partners (61%); the 35 interviewed at test-of-cure visit reported 63/95 (68%) partners notified	Original study included 1032 sexually active men, 18–30 yr, recruited at university in Oslo and Trondheim, Norway; CT tests positive for 81 men; 10% of tests-of- cure were positive confirming need for repeated treatment; men with 3 or more partners more often reported they did not inform all partners compared to men with few partners
Menza et al. 2008 <i>Sex Transm Dis</i> <sup>85</sup>	Retrospective evaluation	313 MSM reported with GC or CT and reported partner information; Seattle and KingCounty in 2004	Reviewed records of all MSM with GC or CT infection interviewed; men asked to indicate if each sex partner was already notified or treated at time of interview and were offered PN assistance	Partners reported by index cases notified and treated; DIS disposition codes	1037 partners reported; information provided for 634/1037 ( 61%); 213/313 (68%) of index patients reported notifying at least 1 partner; index cases reported that 295/1037 (28%) reported partners had been notified and 170 (16%) were treated; DIS disposition codes documented 111(11%) partners tx; only 18 index requested DIS assistance – DIS notified and tx 24/35 (69%) partners reported by those 18	409 MSM with GC and CT; only 313 reported partner information; higher levels of partner tx reported by index cases than DIS disposition codes
Thurman et al. 2008 <i>Sex Transm Dis</i> <sup>41</sup>	Cross- sectional analysis	775 low- income Mexican American and African American women with non-viral STD; age 15–45	Comprehensive intake interview to identify demographics and partner information; statistical analysis to determine factors independently associated with PN	PN; Factors associated with PN; identify women most likely to notify their partners about STI exposure	1122 male sex partners; of the women with 1, 2, or 3 partners, 87.9%, 41.4%, and 25% reported PN for all partners respectively; 5 variables predicted PN committed relationship, 1 partner, recent intercourse, anticipated ongoing sexual activity, desire for pregnancy; patient and partner sociodemographic variables not significantly associated with PN	Among low-income MA and AA women, perception that a relationship was committed was most predictive of PN; only assessed woman's intention to notify and could did not confirm if partner notified and treated
Young 2007 <i>Int J STD AIDS</i> <sup>40</sup>	Prospective evaluation	626 women, age 14–25 years old  Gugulethu, Cape Town, South Africa	Women testing positive for GC, CT, or trichomonas given choice of patient-based partner referral (PBPR) or patient delivered partner medication (PDPM); surveyed about experiences with either type of PN at f/u visit	Effectiveness, acceptability, and feasibility of PBPR and PDPM	PN choices recorded for the 106 women w/ at least 1 STD; 116 reported partners; 99 (85%) chose PDPM; 15 (13%) chose PBPR; 98 (87 PDPM, 7 PBPR, 4 both) of 106 women interviewed at f/u; 94% of partners exposed to PDPM took meds; 92% exposed to PBPR attended clinic for tx	Article includes patients' and partners' attitudes about both forms of PN
Balkus et al. 2006 <i>Sex Transm Dis</i> <sup>86</sup>	Retrospective evaluation (prospective cohort)	333 HIV- positive women who had recently delivered children. Nairobi, Kenya. 1999–2003	Patient referral	Index patient report of partners notified	76% of women using hormonal contraception reported informing partners; 80% of women not using hormonal contraception reported the same	Parent study evaluated HIV vertical transmission intervention. Study results indicate some partners were tested for HIV, implying some partners were notified

(Continued)

Citation/ Quality	Study design	Population and setting	Exposure or intervention	Outcome measures	Principal findings	Miscellaneous design and analysis considerations
Rose et al. 2005 <i>NZ Med J</i> <sup>38</sup>	Retrospective evaluation (chart audit)	77 women attending clinics specializing in termination of pregnancy, New Zealand 2003	Health interview, but partner management strategy unclear	Partners treated	42% (32/77) of women had a partner treated (verified)	Study notes that information on partner management was hard to extract from patient records
Gotz et al. 2005 <i>Sex Transm Dis</i> <sup>29</sup>	Prospective evaluation	165 CT- positive case reports (122 female), Netherlands (national sample) 2002–2003	Patient referral with referral cards, patient and healthcare worker discuss PN and elicit number of partners	Partners treated	86/176 (49%) partners were verifiably treated	A further 28 partners were “potentially” treated, manner of supposition undefined
Penney et al. 2005 <i>Public Health</i> <sup>87</sup>	Random sample-based survey	263 clinicians Lothian/ Grampian, UK 2002	Reported extent to which physicians (or designated staff) discuss PN with CT-infected patients	PN instruction rate	138/263 (52%) physicians reported PN discussions with patients	Survey response rate = 72%
McCadden et al. 2005 <i>Sex Transm Dis</i> <sup>88</sup>	Prospective evaluation (based on national screening sample)	65 CT- positive persons, UK 1999–2001	Cases notified and referred to general practitioner (50) or GUM clinic (15). PN discussed with study nurse and with healthcare provider	Partners notified (combination of clinic/ provider reports and study-related reinterview with patient)	49/65 (79%) patients had notified partners	Treatment verified for a proportion of partners, based on patient report

Notification indices (9 estimates, median = 1.02) ranged from 0.57 for heterosexual men with syphilis in Georgia to 1.65 for people diagnosed with chlamydia in Varmland, Sweden. As a proportion of partners named, figures ranged from 14% in the 8-city study<sup>78</sup> to 81% with HBV partners in San Diego.<sup>76</sup> Five of the 9 figures were above 70%, indicating that DIS or other public health staff found most of the partners they attempted to find. Of the remainder, a Colorado RCT produced figures of 37%, 52%, and 54%,<sup>78</sup> showing the outbreak figures from the 8-city study as an outlier. The actual notification index for that study was 0.94, close to the median; the high contact index (6.8) as a denominator reduced the figure as a proportion of partners named.

Finally, 7 estimates of the brought-to-treatment index (BTI; median = 0.22) ranged from 0.03 for long-standing HIV in San Francisco<sup>75</sup> to 0.93 for chlamydia in Varmland, Sweden.<sup>79</sup> The median is almost identical to the summary figure reported in Brewer's 2005 review.<sup>72</sup> For 3 estimates, all for syphilis, the authors reported infected partners' status according to whether the locating DIS found an infected, untreated partner or one who had been infected, but already treated diagnosed elsewhere at the time of notification. In one study, the BTI (Table 17.2) dropped from 0.26 to 0.09 when previously diagnosed partners were excluded; in the other, 37% of infected partners of heterosexual men and

59% of infected partners of MSM had been diagnosed elsewhere at the time of notification.<sup>75,77</sup> What appears to be a mixture of provider referral and patient referral is a reminder that both forms of referral can complement one another. Each notification strategy in the above examples, however, was reliant on an interview with health staff. This point is borne out further in a Seattle study in which HIV-infected index patients who reported talking to health department staff about partner notification were more likely to notify at least one partner than those who did not (OR = 2.5, 95% CI = 1.6–3.9).<sup>80</sup>

### Patient Referral: The Index Patient as the Medium

In this section, we evaluate studies that simply rely on the patient to notify partners without interviews or the potential for DIS follow-up of partners the index patient does not notify. Beside contact indices when there was some record of partners named, we examined measures of how many patients notified partners and, reported partner treatment rates and, in some studies, the reinfection rate among index cases.

The 12 studies in Table 17.4 come from seven countries and include patient referral efforts for heterosexual men and women and MSM diagnosed with STD including gonorrhea, chlamydial

infection, and trichomoniasis.<sup>29,38,40,41,81–88</sup> Six contact indices based on partners claimed at the time of diagnosis (median = 1.45) ranged from 1.07 for Dutch men and women<sup>29</sup> to 3.31 for MSM diagnosed with gonorrhea or chlamydial infection in Seattle.<sup>85</sup> The proportions reporting notifying partners was quite high (10 estimates: median = 64%), ranging from a low of 25% for women in Texas, US with 3 or more partners to 88% for women reporting 1 partner in the same study.<sup>41</sup> Three of the 4 estimates falling below two-thirds were based on people with multiple partners.<sup>41,81,82</sup>

One lesson from these figures is that patient referral efficacy is reasonable for index patients with a single partner, but drops sharply for those with multiple partners. Another lesson is that choice, again, may play a role in efficacy. The highest treatment rates were reported from a South African study in which women chose either a referral card for each partner (15 women chose a card for at least 1 partner) or medications to bring to a partner (99 chose this option for at least 1 partner).<sup>40</sup> Thirteen of the 15 partners (92%) given a referral card attended a clinic appointment, but comprised only 15% of all partners. The question is whether treatment rates would have been nearly so high had all the male partners been told to come to the clinic via referral card. The principal reason index women gave for choosing patient-delivered partner therapy was that they were not sure their partners would attend. Finally, time spent with an index patient at the point of care is worthwhile. Although we explore this proposition more clearly in Part III, data in a previous review of male index patients suggested that simply raising the prospects and profile of patient referral produced better partner notification outcomes.<sup>6</sup>

## Hybrid Approaches

As mentioned previously, some countries use a mixture of public health intervention, either through trained staff or third party methods (e.g., physicians) and patient referral for partner notification. A 2005 review of partner notification in European Union countries (and Norway) reveals a variety of systems, all of which rely mostly on patients as the medium of notification.<sup>59</sup> Of the 15 systems surveyed, only 5 offered provider referral and only Norway and Sweden mandated any partner notification for reported STDs. Both countries plus six others (the Netherlands, UK, Denmark, Italy, Ireland, and Austria) had published guidelines for partner notification; interestingly, the presence of guidelines does not appear to correlate with countries' geographic location in Europe, the dominant religious doctrine in the country, or the likelihood of a conservatively or liberally-oriented government. Only Spain among those surveyed had no legal status identified and no guidelines for partner notification. In general, countries with specialty clinics for STD tended to have more developed partner notification programs, and staff in specialty clinics tended to know more than others about partner notification.<sup>59</sup> A scan through the reference section of this chapter will show that these factors are also correlated with the amount of public health partner notification research published in these countries.

In the UK, for many STDs, including syphilis and HIV, the physician or health advisor offers assistance and speaks to the need

to refer partners for care during a post-diagnosis conversation or counseling session.<sup>89,90</sup> In some circumstances, patients may ask the provider to handle notification, but a more typical outcome is that the patient takes responsibility for handling notification and referral. The health agency, however, will follow-up with the patient at 4 weeks, usually by phone. During this follow-up conversation, the health advisor will check to see if the patient has notified the partner, sometimes speaking to the partner then and helping ensure he or she is evaluated or treated. When partner identifying information is taken at any point in this process, the health department or agency can evaluate the efficacy of this hybrid method.

Public health contact with index patients in this manner may well improve program levels of partner management (Table 17.5).<sup>91–98</sup> We examined UK audit data from 8 studies published since 2004, the year in which the British Association for Sexual Health and HIV (BASHH) set up national standards. A ninth study<sup>99</sup> covered partner notification among women with diagnosed PID, but numbers were low ( $n = 30$ ), only one-third had STD etiology, and we could not discern the method of partner notification. Twenty of the 30 patients did have their partners notified and treated.

Overall, the audit data revealed substantial heterogeneity in treatment indices (number partners treated per index patient and an important indicator of effectiveness). The range was 0.12 to 0.97, and the median was 0.49. Syphilis featured at both ends of this range. The highest figure was derived from a sample of 101 patients who were offered provider referral. Of the 102 partners named (a contact index of 1.01), 98 were contacted and tested.<sup>94</sup> The lowest figure was for a Newcastle audit of 41 men with almost exclusively casual and largely untraceable partners for whom it was unclear that provider referral was attempted.<sup>95</sup> The audit actually recorded a notification index of 1.68 (19% of all partners), but only 44 tested. The remaining audits were mostly cases of gonorrhea or chlamydial infection. Thanks to audit standards, partner treatment was more likely to be verified through some sort of personal contact with partners or patients than is typically the case in the US for these STDs. The national audit,<sup>91</sup> as well as a 13-clinic audit from the UK Midlands<sup>92</sup> reported similar treatment indices, 0.41 and 0.49, suggesting that the presence of standards alone does not elevate partner treatment to rates sufficient to stem transmission.

## Program Services and Measurement

Two retrospective evaluations of program data point to the usefulness of public health intervention at the point of diagnosis for HIV. As noted under *Provider referral*, a Seattle study showed that a conversation with a DIS (not necessarily DIS follow-up) improved the odds of notification.<sup>80</sup> An evaluation of New York city data compared the effects of clinical providers attempting to perform partner notification from HIV-infected cases against DIS efforts to do the same.<sup>100</sup> DIS elicited more partners and notified 71% of them, versus 48% for clinical providers. Overall, DIS accounted for 27% of new diagnoses against 22% for clinicians, even though DIS saw 206 index patients against 3460 seen by clinicians. With HIV, US testing services do not always offer

**Table 17.5:** Audit Summaries for UK Partner Notification

Citation for audit	Population, STD and setting	PN intervention	Principal PN outcomes measured	Principal PN findings	Miscellaneous design and analysis considerations
McClean et al. 2008 <i>Int J STD AIDS</i> <sup>91</sup>	5032 cases audited throughout UK 2007	Patients counseled about PN	Documentation of PN counseling; partners tested	4577 91% received PN counseling, CT contacts tested (verified) per index case 0.41	
Manavi et al. 2008 <i>Int J STD AIDS</i> <sup>92</sup>	Audit of 13 West Midlands UK genitourinary clinics 2007	Chart review by clinics with case information reported for 10 index cases each of CT, GC Early Syphilis and HIV	Number of partners identified and treated type of partnership (casual or regular)	632 index patients identified 958 partners 283/311 screened partners (91%) were in regular relationship 647 of partners untraceable (majority casual partners)	
Sawyer & Manavi 2007 <i>Int J STD AIDS</i> <sup>93</sup>	231 GC-infected persons (100 female) UK	Review of case notes of culture positive GC infections; including counseling and contact tracing by health advisors	Partners notified	0.33 partners for each GC cases contacted; 77 partners in total notified and managed w/in 4 weeks; 32/131 (0.24) men and 45/100 (0.45) women	
Fernando & Thompson 2007 <i>Int J STD AIDS</i> <sup>94</sup>	101 patients infected with syphilis; 85 men (73 MSM), 16 women; UK	Patient interviewed for partners, health department assistance offered	Partners elicited, contacted and tested	102 contacts identified; 98/102 (96%) confirmed follow-ups with testing and/or tx	
Chauhan et al. 2006 <i>Int J STD AIDS</i> <sup>95</sup>	40 male GUM clinic patients with early syphilis, Newcastle, UK 2002–2003	Patient interviewed for partners, follow-up not specified	Partners notified, tested, cases found	59 regular partners (41 men); 303 casual partners (293 male). Notification index = 1.68 (19% of partners notified); 44 tested; 22 with reactive serologies	Most partners were male casual contacts, study notes most were untraceable. UK Guidelines indicate provider referral should be used <sup>1</sup>
McClean et al. 2006 <i>Int J STD AIDS</i> <sup>96</sup>	781 syphilis patients, UK national 2004	Patient interviewed for partners (78% health advisor, 19% medical provider); patient versus healthcare-based follow-up not specified	Partners notified, treated	683/781 (87%) of patients interviewed; Contact index = 1.28 (997/781); Treatment index = 0.65 (511/781); 51% of reported partners	UK National Guidelines for syphilis management specify only that the patient and provider should discuss who will notify partners and that both options should be available
Evans & Bacon 2006 <i>Int J STD AIDS</i> <sup>97</sup>	STI clinic patients, London, UK 2000–2002	Patient referral instruction (UK guidelines) <sup>1</sup>	Chart documentation of PN instruction; Partner treatment records	88% patients with documented PN instruction; Partner treatment index = 0.45	PN audit part of more expansive periodic clinical care and follow-up audit
Fernando & Clutterbuck 2005 <i>Int J STD AIDS</i> <sup>98</sup>	189 male CT patients at GUM clinics, Edinburgh, UK 2003	Partner interview, follow-up method not specified	Partners notified and/or treated	Contact index = 0.74 (140 partners). 124 partners (89%) verified as tested or epi-treated	Patient referral with health advisor check on progress is typical of CT partner management in UK

partner services. Of 590 patients responding to a survey in Los Angeles and Chicago, 49% reported the testing agency did not discuss partner notification with them, and 61% did not offer DIS assistance.<sup>101</sup> The figures for medical providers from the same study were 34% and 53%, respectively.

With respect to measurements, the availability of relatively standardized data in the UK has made it plausible to compare services geographically and across time. The US has national-level surveillance data for several STDs, including HIV, and healthcare reform prospects in information technology (e.g., electronic medical

records and reporting) may aid population-level measurement there in the future. Some arguments remain in partner notification around data verification.<sup>102,103</sup> Self-reported figures may well be inflated, but requiring third-party verification of all data limits innovation and scope. At its extreme, the requirement is also prone to tautology (if only DIS can verify outcomes in the field, for example, then only provider referral is evaluable).

Much has been made in other medical settings about the needs for protocols and the people to enforce them (with or without audit standards, one Scottish survey found only 52% of physicians in two

Scottish care centers discussed partner notification with patients).<sup>87</sup> South African program evaluations have shown how a protocol introduced in a medium-resource setting can dramatically improve service delivery.<sup>104</sup> Measurement of current practice is the first step, as shown through a Singapore survey in which only a minority of physicians discussed partner notification, although a majority took sexual histories and gave overall counseling.<sup>105</sup> Similar efforts in Vietnam revealed even less basic knowledge,<sup>106</sup> but the good news is that both surveys documented care and infection control deficits with a view to remedying them.

Two final notes conclude this section. During an audit of Australian data, England and colleagues noted that health department-based partner notification better than doubled the number of partners seen (verified!), but took almost 7 hours per partner.<sup>107</sup> They noted that cost considerations needed to be taken into account alongside efficacy–cost effectiveness is important. Second, this quote from British auditors illustrates how measurements of either effectiveness or cost effectiveness need to speak to outcomes: “Compared with auditing outcomes, audit of management policies overestimated performance in contact tracing...”<sup>96</sup>

### Part III: Innovations in Partner Notification

Innovations in partner notification are often explained in the provider and patient referral terms we have used to categorize practice.<sup>108</sup> This split, however, may reflect a US-centric bias based around the history of the heavily public health investigator-centered syphilis partner notification approach and the modal reliance on patient referral with minimal accompanying intervention for infections such as chlamydial infection. As illustrated in the previous section, partner notification internationally today is performed through collaborative hybrid approaches. In the US, much innovation takes this form, including public and private cooperative efforts.<sup>8</sup> Therefore, we have described innovations into categories that require direct public health involvement *in the notification process*, and those that rely on the patient as the direct means of notification. IPN has provider and patient referral versions, and we have discussed those in a separate section.

#### INNOVATIONS IN PUBLIC HEALTH PARTNER NOTIFICATION PROGRAMS

Even though the principles of interviewing index cases and tracing their partners have been put into practice for decades, there is still room for innovation. Some of the most important innovations come in the form of policy changes. When New York state changed to name-based HIV reporting accompanied by partner notification, many people feared fewer people would get tested. However, testing rates remained stable and more people could then receive partner notification interventions for HIV.<sup>109</sup>

#### Interview Enhancements

Brewer and colleagues tested the concept of memory aids to improve recall of partners through an RCT in the Colorado

Springs STDs program in 2000–2001.<sup>78</sup> Brewer et al. tested 3 enhancements to the routine partner interview: (i) a combination of common locations where people meet partners, relationship roles, network ties and first letters of names; (ii) common first names; and (iii) a list of physical characteristics (the control condition). The first set of enhancements yielded approximately one extra partner per two index patients interviewed, versus approximately one for every four interviewed in the other two conditions. The first condition led to a statistically significant increase in the number of partners located per index patient, compared to the third condition.

Notably, each condition was designed to elicit further partners that the index patient had *forgotten*, that is, there is no presumption of lying or prevarication required. Also, of 55 index patients initially reporting 1 partner who were enrolled in the study in its early stages, only 1 reported a further partner. Therefore enrollment was subsequently constrained to those initially reporting multiple partners. Although a review of the literature revealed no replications in the United States, Brewer’s methods have been replicated in Brazil. Public health staff in an HIV testing facility in Rio de Janeiro used location cues, social roles, the alphabet and demographic cues to stimulate memories of partners not initially recalled by index patients.<sup>110</sup> As with the Colorado Springs population, recall of additional partners was confined to those with multiple partners already named: of those with 2 or more partners, 7% recalled at least one more after staff applied the intervention. Among those with 4 or more partners, the cues yielded additional partners from 18% of index patients.

#### Field-Delivered Therapy

Beyond improvements to interviewing, some programs have tested the effects of giving DIS more tools to use during field investigations. One simple innovation is the practice of taking medications out into the field to administer to notified partners: field-delivered therapy (FDT). In some areas of the United States, public health nurses act as DIS, in which case the partner can receive some sort of clinical evaluation before being offered the medication. Even if this is not the case, however, the field investigator can ask some questions (e.g., about prior medication allergies) and observe the administration of oral single-dose medications, thus ensuring partner treatment. In San Francisco, insufficient rates of partner treatment for gonorrhea and chlamydial infection led program staff to permit DIS to take single-dose medications into the field to give to partners, when located.<sup>111</sup> “Partner packs” included the treatment, instructions, and preventive items such as fact sheets, clinic contact information, and condoms. DIS typically contacted partners by phone and arranged a meeting. At that meeting, the partner could ask questions and take the medication; the DIS could observe for adverse events and provide counseling and education. No further contact was required. Treatment rates rose from 62% of 432 partners assigned to DIS in 1998 (all clinic-based treatment) to 81% of 630 partners in 2000 (67% clinic, 14% FDT), a 31%

increase,  $p < 0.001$ . The increases held broadly across gender, age, and race, with the exception being for MSM, among whom nearly all cases (93%) had been treated in 1998, that is, prior to FDT implementation. A subsequent study from San Francisco incorporating FDT into services for homeless youth found high acceptability and minimal reinfection.<sup>112</sup>

## Network Analysis in Partner Notification

Incorporating social contacts into the partner notification investigations is not a new concept, dating back to instructional manuals for decades.<sup>113</sup> Retrospective analyses of the links among infected persons, their sex (or drug-using) partners, and sundry social contacts has sometimes yielded a more complete portrait of STDs in a given community and provided information useful for public health-mediated partner notification efforts.<sup>114,115</sup> A UK evaluation based on a single HIV-infected person resulted in a network of 123 people, all sex partners or partners of sex partners—15 previously undiagnosed HIV-infected people, 11 previous positive HIV cases, and 4 cases of syphilis.<sup>116</sup> Partner notification was accomplished through a mixture of provider referral (104 cases, 71% success, 55% with known outcomes) and patient referral (19 cases, 79% with known outcomes).

Even more obviously useful are prospective efforts using network techniques, although STD program resources and expertise often make such efforts difficult. One example is an Atlanta syphilis outbreak from the late 1990s, in which DIS performed interviews for partners as per normal practice, but also spent extra time (up to 80% of total hours) in street settings, interviewing index cases and others for drug use partners and important social contacts.<sup>117</sup> These additional contacts were encouraged to seek testing. Forty-eight index patients named 130 partners, of whom 30 were infected, and 153 other contacts, of whom 9 were infected. Contacts of uninfected persons yielded 6 infections from 113 sex partners and social contacts. This 5% prevalence of syphilis is high for a rare disease in the US, and the extra 15 cases generated from the network interviewing added 50% to the 30 cases found through basic provider referral (the yield from provider referral was certainly much higher). A more recent evaluation in British Columbia introduced social network interviews and mapping of cases during a syphilis outbreak.<sup>118</sup> The addition of network information in this investigation showed that more cases were linked to one another (24% vs. 32%,  $p = 0.03$ ), improving public health ability to manage the outbreak.

Network analyses in Atlanta and British Columbia revealed some people who were central to the overall sociosexual network. Such individuals could be interviewed in later outbreaks or even periodically without outbreaks to produce a more efficient series of investigations over time. The process, done well, could also bring community members into the case-finding process, essentially acting with public health rather than as the object of an investigation.

Two final examples show what can be done with patients acting as the agents bringing in social contacts for testing in programs operated by health departments. In Seattle, US, an evaluation

of “patient-driven cluster referral” presented infected persons in STDs clinic the option of referring for testing up to 3 others who they thought would benefit from testing.<sup>119</sup> Those making referrals received a modest amount of cash, as did those who presented for testing. People who referred infected persons could then recruit others, as could those who were tested. The method revealed a 5% rate of previously undiagnosed HIV among those tested, as well as 31% with HCV (excluding known positives) and 8% with gonorrhea. Cost per case of HIV detected was \$4939, compared to over \$11,000 for CBO-based counseling and testing services in the same area and time period.<sup>119</sup> A similar approach with HIV-infected persons recruited through community-based organizations offering HIV testing and referral in several east coast US states yielded a 6% rate of previously undiagnosed HIV among those referred for testing.<sup>120</sup> Although patient-mediated efforts to use network approaches preclude some analyses—not all components can be connected without further interviewing—the method is inexpensive and can be used to complement routine DIS interviews and provider referral (as was the case in Seattle).

## INNOVATIONS NOT REQUIRING DIRECT PUBLIC HEALTH INVOLVEMENT

For the most part, innovations that do not require public health involvement are innovations in patient referral. EPT is probably the most widely known of these innovations in recent years, although certainly not the only novel approach. EPT, which encompasses a series of models in which partners of index cases are offered treatment *without* a prior clinical evaluation. FDT, as discussed above, falls into this category if the field agent is not a clinical provider (e.g., a public health nurse). More often, the index patients bring medications or prescriptions for medication to their partners, most commonly known as patient-delivered partner therapy (PDPT). A hybrid model in the UK is known as accelerated partner therapy (with the felicitous acronym of APT). In APT, health advisors conduct an initial interview with patients and provide options for partners to have some contact with healthcare professionals (phone or pharmacy) before receiving medications.<sup>121</sup>

The goal of the various versions of EPT is to increase the proportion of partners treated, thus curing infection and stemming transmission (including reinfection of the index). One clear sacrifice is the knowledge of whether one is treating an infected partner or treating on a prophylactic basis (epidemiologic treatment). A potential sacrifice is the loss of other information gained in a clinical follow-up: coinfections not treated by the medication administered through PDPT, the opportunity to counsel partners, and the opportunity to ascertain risk factors such as medication allergies. Some of these issues can be obviated in FDT if the field agent is qualified, for example, to assess for allergies. Nevertheless, PDPT in particular needs to be confined to circumstances in which serious adverse reactions to medications are very rare. This is the case with azithromycin (used to treat

chlamydial infection) and the third-generation cephalosporins used to treat gonorrhea—at least in the US and other countries that can afford public health infrastructure. PDPT should also be accompanied by instructions on taking the medication, for corollary care associated with treatment (e.g., for how long to abstain from sexual activity after treatment), and encouragement to seek clinical care.

Between the mid-1990s and 2003, CDC sponsored four RCTs testing EPT efficacy among male and female heterosexual patients infected with chlamydial infection, gonorrhea, and trichomoniasis.<sup>69,122–124</sup> These RCTs have been reviewed on several occasions.<sup>125–127</sup> Here, we emphasize that the RCTs were conducted in several different settings (including six geographically dispersed cities in the first trial), with some variance in operational details. Nevertheless, the principal outcome measure, reinfection in the index patient assigned to EPT relative to patient referral, was quite consistent across trials. For example, the patients in the PDPT arm of the Seattle RCT received prescriptions and were offered DIS assistance; those in the New Orleans urethritis RCT (a majority of which was based on gonorrhea) received medications and counseling.<sup>69,123</sup> The reduction in reinfection (gonorrhea-only in Seattle) in both settings was close to 50%. Seattle and six-city RCT data for chlamydial infection, if expressed as odds ratios, were identical to two decimal places.<sup>69,122</sup>

The strength of EPT, based on US studies, is the robustness of the effects across different settings, at least where gonorrhea and chlamydial infection are concerned. The Seattle RCT in particular also illustrates a point about the value of placing an intervention with a public health goal in a realistic program setting. That is, outside the parameters of a RCT, a patient who asks for DIS assistance in a public clinic should get it; so a trial that includes that programmatic reality has more external validity and more chance of being translated into other STDs programs than one that does not. Research that incorporates program-relevant questions and realities into the actual conduct of efficacy research has more chance of attaining the broader goals of effectiveness and impact: points recently encapsulated in STDs prevention research as “program science.”<sup>128</sup>

The most recent work in the US comes from a second RCT with 484 female index patients, this time comparing PDPT versus DIS-assisted referral versus patient referral.<sup>129</sup> Importantly for estimating reinfection, this RCT included a test of cure at 9 days: 95% of the patients were negative for trichomoniasis at that point. Index patient reinfection rates with 61% follow-up were not significantly different among the arms at one month, ranging from 5.8% (PDPT) to 15.0% (DIS). At 3 months (but only 40% follow-up), the percent positive in those two groups were almost reversed, with 14.3% in the PDPT arm and 7.8% in the DIS arm. Although the 3 month comparisons between groups are confounded by differential treatment rates at 1 month, the reinfection rates (approximately one-sixth of those seen by 90 days) do illustrate how easily people can become reinfected. The authors estimated 34% of partners were treated from those cases they could verify; together with reinfection rates, these data

show how inadequate partner treatment fails to stem infection control in a population.

As the preceding paragraph shows, the large majority of the efficacy research has taken place in the US. The British APT model is tailored to the existing partner management approaches in the UK and contains elements of PDPT, but also FDT.<sup>121</sup> That is, the two APT models currently in UK testing rely on the existing health advisor contact at the time of diagnosis and treatment. The health advisor conducts an interview with the index patient that includes a history of sex partners. In one model, the patient then immediately phones the partners, who speak via telephone with the advisor, who conducts an assessment. The patient can then leave with medications (and an optional self-test kit for gonorrhea and chlamydial infection). The patient also carries instructions for taking medication and a referral for the partner to attend the clinic for further evaluation. The second model has the assessment of partners mediated through pharmacies: the index patient is given a referral card for each partner, and the partner can receive an assessment, medications and a self-test from a local community pharmacist. In both cases, a health professional is able to speak directly to the partner before dispensing medication. In neither case does the partner have to visit a clinic, although the visit to the pharmacist is presumably similar in some costs.

Interviews with 37 patients revealed the options were broadly acceptable and appreciative of the perceived efficiency, with a majority preferring the phone model, as if in the role of the index patient.<sup>121</sup> In the role of the partner, opinion was split. Some barriers raised to the phone call model were related to the potential shock value of the notification: is the partner aware the patient went to the clinic; will the partner have a private place to talk; and a general preference among some patients for personally notifying the partner. Although this last preference is generally positive with respect to successful notification, it essentially nullifies the prospects for APT. Some felt receiving treatment at a pharmacy would be less embarrassing than at a clinic, although others felt it would actually be worse (less private) and thought the pharmacists would not be suitably skilled to deliver counseling. Respondents, however, perceived the pharmacy model as an answer to some of the barriers in the phone call model, so the choice between the two is likely to provide greater coverage and superior prevention impact to having a single model. What is required for APT now is evidence of efficacy, with exploratory trials pursuant to a RCT currently underway.<sup>130</sup>

The spread of EPT in the US continues as an increasingly regulated activity, as opposed to the largely unregulated but widespread use identified in a 1999–2000 national survey.<sup>3,131</sup> Many relevant medical organizations support EPT as an option, including the American Medical Association, Society for Adolescent Medicine, and the American Bar Association. The number of states that either explicitly permit EPT or that appear to have no legal impediments to its practice has risen from 11 in 2005<sup>132</sup> to 21 in late 2009. The number of states with prohibitions (not aimed expressly at EPT, but certainly

applicable) has fallen from 13 to 8. Patient surveys suggest PDPT in particular is acceptable to clinic attendees as a concept,<sup>133–135</sup> although factors such as costs certainly affect uptake.

Nevertheless, EPT, especially as PDPT, faces ongoing operational barriers. Concerns about adverse reactions for patients persist. Because those concerns are typically the first mooted by people who have not considered EPT, the data on the lack of serious adverse reactions to medications is reassuring to many. California and Washington, two states that have maintained several years of efforts to assess serious adverse events through hotlines (phone and e-mail versions), have not recorded one. Other concerns pertain to incomplete care—essentially that partners who receive medication will avoid seeking more comprehensive care. Some skepticism is correlated with institutions' ability to manage partners through other methods. A survey of New York state local health departments showed that health departments with fewer resources to trace partners were more favorably disposed to PDPT.<sup>136</sup> A British survey revealed that 50% (again) of 206 genitourinary medicine physicians surveyed had used PDPT and that two-thirds of physicians were favorably inclined toward using PDPT for chlamydia.<sup>137</sup> However, a much lower proportion (24%) favored PDPT for gonorrhea, and health advisors, who were also surveyed, felt less positively toward PDPT in general (21% had ever used PDPT).

The authors<sup>137</sup> also collected quotes from respondents: these mirrored early concerns advanced in the US, including some views of PDPT as unsafe: "I believe PDPT is unsafe;" as a competitor with other interventions, "It undervalues the role of sexual health interventions including risk reduction strategies;" possibly as a competitor for jobs, "It is a cheaper option to spending money on health advisors;" and as an all-round harbinger of doom, "Do not go down this slippery slope!" Without drawing too firm a conclusion from individual quotes, some respondents appear to construe PDPT as something of a job threat, or as a threat to public health or clinical practice. One notes that the UK has a relatively well-developed and evaluated infrastructure including measuring partner outcomes—in Brazil, attitudes were far more positive, with researchers specifically noting the need for some methods to help control STDs rates with which public health simply could not keep up.<sup>138</sup> Elsewhere, Arthur and co-workers' review of partner notification in Europe<sup>59</sup> showed that EPT (referred to as patient-expedited therapy) was used in approximately half of the countries surveyed, but almost always in less than 10% of cases, and typically only for chlamydial infection. Not that national program responses, as in this survey, are a perfect guide to clinical practice: the flat "No" reported for the UK contrasts against published references to the practice from the same year.<sup>88</sup> The same was true in the US, where responses from state medical and pharmacy boards<sup>139</sup> were uncorrelated with reports of clinical practice.<sup>131</sup> Finally, although neither Greece nor Spain were counted as practicing EPT, antibiotic treatment there was available over the counter in 2005, suggesting that at least some patients brought medications to partners (or the partners got them) without a prescription, let alone a clinical evaluation.

An editorial accompanying Trelle and co-workers' 2007 systematic review<sup>125</sup> specifically named patients' difficulty disclosing (i.e., notifying) partners of their exposure as a key unmet need, and one that required counseling.<sup>140</sup> The point is pertinent, as many patients are asked to notify partners with no tools or counseling around how to do so. Trelle et al.'s analysis covered several counseling and educational interventions with the conclusion that some combination of written and verbal information improved outcomes for patients and partners, although simple randomized comparisons between basic patient referral and patient referral with counseling enhancements were infrequent. One Zimbabwean RCT with an interactive partner notification counseling session demonstrated improved notification rates for men (1.8 partners notified versus 1.2 in the control group), but not women (0.7 in each group).<sup>141</sup>

Theory-based counseling at the time of diagnosis has recently been shown to help reduce reinfection among patients diagnosed with STD in clinics. A US RCT in Brooklyn, New York was designed to test the effect of counseling patients about patient referral on reinfection (with chlamydial infection or gonorrhea).<sup>142</sup> The aims of counseling were to increase the patients' motivation to notify their partners and prepare them with the specific skills to do so, constructs derived from social cognitive theories of behavior that have been applied to sexual risk and STDs prevention before.<sup>143–145</sup> Participants received counseling that included discussion of behaviors that could have led to infection, development of a partner notification plan for each partner identified, role playing exercises, and signature of a contract to execute the plan. Patients took written materials with them, including referral cards and a summary of steps to successful partner notification as discussed with the counselor (nothing wrong with a cheat sheet here!). A second session was designed to take place by phone or in person at a target of 4 weeks from the initial session; this session centered around a progress review and barriers to completion, if any. This second session was similar to the UK structure with counseling and follow-up.

Partner notification rates were high in both RCT conditions (86% control, 92% experimental; OR = 1.8, 95% CI = 1.02–3.0), but reinfection rates, the primary outcome, were substantially lower in the experimental arm (6% vs. 11%; OR = 2.2, 95% CI = 1.1–4.1). The RCT showed larger effects for men than for women, who had higher base rates of notification and therefore less room for increased rates as a group.

One useful point to note for programs considering implementation or replication is that the authors conducted pre-RCT formative research to identify beliefs and opinions among the target population that were salient to partner notification. The principle is applicable to any replication, but the specific salient beliefs might easily differ by locale (especially if one considers international dissemination). For programs with infrastructure including DIS, we note that these staff should be ideal collectors of precisely this formative data. We also note that basing a largely behavioral intervention on sound social science principles is a benefit to the recipients and to public health.

## INTERNET-BASED PARTNER NOTIFICATION (IPN)

With the emergence of nearly every new technology comes the challenge of adopting and adapting it for intervention, including using new technology to reduce infrastructure and service gaps between economically developed and other countries.<sup>146</sup> In the US, the internet as a venue for sex seeking began to draw real attention in the late 1990s.<sup>147</sup> In 2000, the San Francisco City Health Department used e-mail or chat room handles to contact partners of 6 MSM diagnosed with early syphilis.<sup>148</sup> The men named approximately 12 partners per index case, of whom 42% (notification index of 5.9) were located through internet contact. Other studies revealed similar results,<sup>149</sup> confirming that when the only identifying information of an anonymous partner is an e-mail address or screen name, the internet, however tenuous, is the only viable means for reaching these cases for partner notification.

Many health departments recognized the need to adapt traditional DIS activities to the internet, and CDC encouraged health departments to adopt the internet as a tool for partner notification and STDs prevention. CDC also funded the National Coalition of STD Directors (NCSDD) to develop a national set of guidelines for internet-based partner notification<sup>150</sup> and has yet more recently required jurisdictions receiving STD prevention funding to form IPN protocols. To date, approximately half of US states use IPN in some form or another, although bureaucratic obstacles and lack of infrastructure or trained staff continue to pose barriers. Where there are no public health IPN services, partner notification remains the province of patient referral.

A Texas, US study assessed the effectiveness of internet provider referral for 177 partners of 53 men (contact index = 3.34) for whom the DIS had only e-mail addresses, comparing the efficacy to standard provider referral.<sup>17</sup> With e-mail only, DIS notified 50% of partners and were able to bring to treatment 80% of those notified. Provider referral with phone or personal contact was more efficacious, (70% notified and 95% of those notified brought to treatment), so presumably a program would use those methods, if available. However, the grand total of 40% of partners evaluated, a BTI of 1.34, is a good deal better than 0 (the alternative with no protocol). Furthermore, the authors note that use of IPN allowed for rapid communications and required no additional field work or after hour work for staff.

The District of Columbia, US analyzed STDs program disposition codes (the accounting framework for reporting endpoints of case investigations) and found that incorporating IPN into current efforts increased outcome indices including notification, and treatment.<sup>151</sup> Among 286 patients with early syphilis who were interviewed by DIS, 88 (31%) reported a sex partner met via the internet. IPN increased the overall total number of cases investigated by 75%. Indices for new treatment and new exams increased by 22% and 26%. The authors concluded that using the Internet allowed them to notify at least 75% of the internet partners of their STD exposure, allowing them to reach previously untraceable sex partners.

One twist on IPN is to offer an internet-based proxy for the DIS interview. The Houston Health Department offers a confidential, computer-based option to index patients that mimics the typical DIS interview, [www.penshouston.org](http://www.penshouston.org). The health department has partnered with local community-based organizations (CBOs) and private providers to encourage use of the website among syphilis positive patients, in addition to offering the online service to patients resistant to traditional partner notification efforts. To date, no evaluation of the system has been conducted due to a lack of funding.

Patient-based IPN approaches include web-based systems such as InSpot.<sup>18</sup> InSpot began as a response to a San Francisco needs assessment in which respondents (mostly MSM) reported that they would be likely to notify a primary partner of an STD exposure, but less likely to notify casual partners. Additionally, when asked if they would use an anonymous online partner notification system if one were made available to them, many stated that they would. InSpot users log on and choose an electronic postcard (e-card), specify an STD, add a personalized message (if desired) and can send the e-card to up to 6 different e-mail addresses. The user also has the option of sending the e-card anonymously or from a personal e-mail address. In 2006, the designers released an updated version of the website to be used by all audiences.

Currently, anyone in the world can use InSpot for IPN, but various jurisdictions have purchased the system to add local resources. An evaluation of website metrics found that since 2004, over 30,000 users have sent over 45,000 notifications.<sup>18</sup> Fifteen percent of cards were sent for gonorrhea, 15% for syphilis, 12% for chlamydia, and 9% for HIV. The remainder was sent for "other" STDs, including a proportion naming crabs (typically thought to be an indicator of facetious use). Of those receiving an e-card, between 27% and 29% have clicked on the e-card for additional information.

What remains to be seen is whether receipt affects referral rates; that is, does testing follow receipt? A Colorado clinic-based study found little use by largely heterosexual men and women attending clinics (<5%), despite numerous marketing attempts including palm cards, newspaper, radio, and internet ads, few clinic patients had either heard of or used the service.<sup>152</sup> An Australian qualitative study also found internet-based methods less acceptable to heterosexual clinic attendees,<sup>153</sup> with many respondents finding IPN in lieu of in-person notification to be essentially failing a responsibility. These findings tend to be conflated with relationship length and ease of notifying a person directly—both MSM and heterosexual populations are more attentive to personally notifying longer term partners and less so for casual partners.<sup>154</sup> Populations with more causal partners and more internet partners are more likely to use IPN independent of their preferences with primary and casual partners.

Finally, social networks such as MySpace and Facebook have also become avenues for IPN and for improving the outcomes of partner notification in general. Users of social networks often post pictures of themselves online, in addition to other locating information such as city, work or school affiliations and mobile

phone numbers, providing DIS with additional identifying information. Unlike a standard e-mail address, contacting a person via a social networking site typically requires the person conducting IPN to establish a profile on that site. Aside from the well-known social network sites above, sites often used for sex-seeking also have similar requirements. Some sites permit free profiles for public health agents for partner notification purposes, facilitating infection control through collaboration. A profile also allows the notified person to learn something about the DIS and the health services offered.

## Conclusions

The role of partner notification in prevention impact is to get enough partners notified *fast enough* to disrupt networks and stem further transmission. In prevention impact terms,<sup>12,13</sup> this means getting sufficient coverage with a sufficiently efficacious intervention. The third element of prevention impact, the contribution of the population to morbidity may be assumed to be sufficient because the index patients are 100% infected.

We conclude, therefore, with observations about how to ensure that there is enough coverage with enough efficacious interventions, realizing that partner notification is one contribution to the intervention mix. As context for these observations, we note that some experts in partner notification have agitated against the drift of much partner management into various versions of patient referral. In the United States, the federal public health advisor corps had, by the early 2000s, shrunk by approximately 60% compared to the late 1980s, while the number of STDs for which they were responsible had increased dramatically. Personnel and other resource conflicts between managing syphilis and gonorrhea during the early 1990s illustrate this issue. In fact, the core area interview approach in New York state<sup>53</sup> originated as an effort to accommodate the detailing of DIS involved in gonorrhea control to syphilis control efforts. Resources have been a source of stress for a long time: a table footnote in Wigfield's 1972 review reads "the comparable figure [to 502] for 1960 was 242. In 10 years the work has doubled; the staffing is static."<sup>64</sup> Some things never change.

We also note some present issues affecting partner notification have been previous concerns. For example, the current issues with ability to locate partners over the internet mimics the concerns expressed for syphilis partner notification among drug-users in the US epidemic and rise in syphilis during the late 1980s and early 1990s. The authors of an evaluation of partner notification in Oregon concluded that "Because patients infected with syphilis have relatively large numbers of anonymous sexual encounters, prevention strategies that supplement partner notification are urgently needed to control the syphilis epidemic..."<sup>155</sup>

A larger dedicated group of public health advisors would almost certainly help in most countries, whether their first purpose were to introduce protocols, train local staff to perform provider referral, or something else. However, public health agencies have little choice but to accommodate patient-mediated

interventions, and the US is certainly unlikely to return to a time in which, say, most diagnosed gonorrhea is followed up by DIS. Instead, the field needs to continue to stay abreast of factors influencing coverage, including technological innovation (text messaging as a medium of notification), population mobility, forced or voluntary, and, perhaps most important, the ability to ensure some form of partner notification remains a part of STD prevention programs that are integrated with other services. Ten years ago, US national level data showed that a large majority of STDs were diagnosed outside public settings,<sup>156</sup> which necessitates prevention in those same settings. When an efficacious innovation in partner notification (e.g., EPT, brief counseling) is adapted to work in the settings in which STDs are diagnosed, one has moved toward sufficient coverage and sufficient efficacy in an infected population: prevention impact. Whether in the service of reducing disparities in an economy with long-standing public health infrastructure<sup>157</sup> or as part of HIV healthcare in an economy with currently increasing public health capacity,<sup>158</sup> multiple interventions in multiple healthcare settings seems not just the future of partner notification, but increasingly the present.

## Implementation of STI Programs

Gabriela Paz-Bailey • Jerry Owen Jacobson

### Introduction

Close to a million people acquire a sexually transmitted infection (STI), including the human immunodeficiency virus (HIV), every day.<sup>1</sup> In pregnancy, untreated early syphilis will result in a stillbirth rate of 25% and be responsible for 14% of neonatal deaths—an overall perinatal mortality of about 40%. Syphilis prevalence in pregnant women in Africa, for example, ranges from 4% to 15%.<sup>2</sup> The sequelae of STIs include acute symptoms, chronic infection, and serious delayed consequences such as infertility, ectopic pregnancy, cervical cancer, and the untimely deaths of infants and adults. The presence in a person of an STI such as syphilis, chancroidal ulcers, or genital herpes simplex virus infection greatly increases the risk of acquiring or transmitting HIV. Despite this evidence, efforts to control the spread of STI have lost momentum in the past 5 years as the focus has shifted to HIV therapies.<sup>3</sup>

Prevention and control of STIs should be part of comprehensive sexual and reproductive health services in order to contribute towards the attainment of the Millennium Development Goals<sup>4</sup> and respond to the call for improved sexual and reproductive health as defined in the program of action of the United Nations International Conference on Population and Development (Cairo, 1994).<sup>5</sup>

This chapter contains recommendations for the implementation of national STI programs. It covers issues on policy framework, program management and structure, essential components of an STI strategy, and considerations regarding program scale-up.

The first section of this chapter addresses the need for national reproductive and sexual health strategies that provide the organizing framework for policies, laws and programs related to STIs including HIV. It also discusses the importance of integrating sexual and reproductive health and HIV services in different settings and the need to identify and review policies and regulations that hinder access to STI and sexual and reproductive health services. Integration issues are explored in depth in Chapter 19.

The second section discusses the steps needed to develop a strategic plan for a national STI program and to develop health

systems capacity, including situational assessment, determination of program priorities, and design of strategies. The third section deals with STI program components, including methods to promote healthy sexual behavior, protective barrier methods, and effective and accessible care for STIs. STIs occur with the highest frequency among marginalized populations who have unique problems in accessing healthcare services. Securing the level of support to provide effective interventions to these groups is especially challenging, though the public health benefits are substantial. Emphasis in this section is placed on a public health approach based on sound scientific evidence and cost-effectiveness.

The final section examines strategies for overcoming common limiting factors to program scale-up, how scale-up may influence cost and the emerging literature on the impact of expanding specific STI programs on broader health systems.

### Policy Environment

Countries should have a national reproductive and sexual health policy to provide an organizing framework for the development of laws and programs related to STIs including HIV. In turn, national policies should be aligned with internationally agreed-upon reproductive health strategies and aim to contribute to international health targets. WHO's reproductive health strategy rests on internationally recommended instruments and declarations of human rights, including the right of all persons to the highest attainable standard of health; the basic right of all couples and individuals to decide freely and responsibly the number, spacing, and timing of their children and to have the information and means to do so; the right of women to have control over, decide freely and responsibly on, matters related to their sexuality, including sexual and reproductive health, free of coercion, discrimination, and violence; the right of men and women to choose a spouse and to enter into marriage only with their free and full consent; the right of access to relevant health information; and the right of everyone to enjoy the benefits of scientific progress and its applications. In order to ensure that

these rights are respected, policies, programs, and interventions must promote gender equality, and give priority to poor and underserved populations and population groups.<sup>3</sup>

National policies and programs should also contemplate how best to link sexual and reproductive health, STI and HIV services in different settings.<sup>3</sup> While evidence that well-designed HIV responses can and do strengthen health systems is encouraging,<sup>4</sup> nonetheless, evidence suggests that greater and more systematic efforts must be made to take HIV responses out of isolation to support wider health, development and human rights agendas.<sup>6</sup> There are several linkages among HIV, STI, sexual and reproductive health responses. For example, services to virtually eliminate mother-to-child HIV transmission provide an ideal platform to deliver the recommended minimum package of antenatal, maternal, child and reproductive health services. Such services would ensure that pregnant women are not only offered HIV screening, but that they and their partners are also offered services to prevent acquisition of HIV and other STIs, unintended pregnancies and sexual violence.<sup>6–8</sup> Interventions to control STIs in family planning clinics, antenatal and maternal and child health clinics would further expand opportunities for prevention, detection, treatment and thus STI control.<sup>3,9–11</sup> For further reading the United Nations Population Fund (UNFPA) has produced guidelines and recommendations on how to improve linkages between sexual and reproductive health and HIV.<sup>12–18</sup>

Calls for integration of HIV services with reproductive health services are not new. Global consensus in this respect was reached as early as 1994 with the International Conference on Population and Development's Program of Action<sup>5</sup> and has been repeatedly reaffirmed in subsequent global declarations, notably the United Nations Political Declaration on HIV/AIDS of 2006.<sup>3</sup> Such political commitments have provided motivation on a programmatic level to take the HIV response out of isolation. Thus, HIV initiatives such as the International Health Partnership, President Obama's Global Health Initiative, the United States President's Emergency Plan for AIDS Relief, the joint approach of the Global Fund to Fight AIDS, Tuberculosis and Malaria, and the World Bank and the GAVI Alliance now support actions toward sustainable and cost-effective health systems more generally.<sup>11</sup> As international HIV strategies adopt a broader health-strengthening perspective, it remains imperative to renew the commitment to controlling all STIs. National STI programs, in turn, should incorporate evidence-based public health policies for treatment and prevention, emphasizing effective integration of sexual and reproductive health services with HIV services.<sup>10</sup>

When evaluating the policy framework it is important to consider that, in some countries, laws, policies, and regulations can serve as obstacles to effective STI program provision. For example, they may hinder access to services (e.g., laws governing sex work, homosexuality, or drug use), limit the roles of health personnel (e.g., preventing nurses from performing HIV testing), bar services (e.g., restrict access to STI and family planning services for adolescents) or restrict the importation of essential

drugs and technologies. STI program managers should identify and advocate for improvement of laws or policies that result in restricted access to, or reduce the effectiveness of, STI prevention and control efforts (Box 18.1).<sup>19</sup> Elimination of unnecessary restrictions from policies and regulations and steps toward creating a supportive framework for reproductive and sexual health are likely to contribute significantly to improved access to services. Regulations are needed to ensure that commodities (medicines, equipment and supplies) are made available on a consistent and equitable basis and that they meet international quality standards. In addition, an effective regulatory environment is needed to ensure public and private sector accountability for providing high-quality care for the entire population.<sup>10</sup>

As a precursor to advocating for policy changes, common misconceptions regarding STI programs must often be dispelled before certain issues can be included in the policy agenda.<sup>7</sup> For example, curriculum-based sex education does not increase risky sexual behavior as many fear, and trends towards early and premarital sex are neither as pronounced nor as prevalent as some believe.<sup>20</sup> On the contrary, systematic reviews have shown that school-based sex education can lead to improved

#### Box 18.1 Policy Environment

##### Resources for STI prevention and treatment

- Budget allocations for STI treatment relative to other diseases.
- Private sector commitment to STI care.
- Provision of the recommended antibiotics to public sector clinics and inclusion of effective antibiotics on essential drug lists.

##### Restrictive policies and procedures

###### Women

- Policies that restrict access to services and require a husband's permission for examinations, intake of drugs or use of barrier methods.

###### Youth

- Policies that restrict access to clinical services for STI and family planning.
- Policies that restrict access to condoms.

##### Condoms and STI drugs

- Tariffs that make importation costly and cumbersome.
- Restrictions on distribution of condoms to minors or unmarried women.

##### Service access

- Restrictive laws that prohibit diagnosis and treatment of STIs by non-medical health personnel, decreasing access to services.
- Policies that encourage clinic-based, laboratory-dependent and physician-managed STI services exclusively.

##### Human rights

- Laws that push risk behavior "underground" or make it hard to communicate with vulnerable people.
- Laws that permit or encourage discrimination against people living with HIV.
- Laws that increase vulnerability to infection or its consequences, including those relating to imprisonment.
- Constitutional or national principles that reinforce or contradict commitments made in international agreements.

Note: Adapted from Dallabetta G, Laga M, Lamptey PR, eds. *Control of Sexually Transmitted Diseases, A Handbook for the Design and Management of Programs*. 1st ed. Arlington, VA; 2001.

### Box 18.2 Evidence of Educational Policies on Abstinence and STI Rates in the United States

A recent study in the United States evaluated the relationships between state-leveled educational policies and STI rates. The authors analyzed US case reports of gonorrhea and chlamydial infection for 2001–2005 against state policies for abstinence coverage in sexuality education. They also tested for effects on 15–19 year olds versus 35–39 year olds and tuberculosis rates, to ensure findings applied only to STI. States with no mandates for abstinence had the lowest mean rates of infection among the overall population and among adolescents. States with mandates emphasizing abstinence had the highest rates; states with mandates to cover (but not emphasize) abstinence fell in between. These effects were not shown for tuberculosis. The authors conclude that having no abstinence education policy has no apparent effect on STI rates for adolescents. For states with elevated rates, policies emphasizing abstinence show no benefit.<sup>92</sup>

awareness of risk, knowledge of risk reduction strategies, increased self-effectiveness, intention to adopt safer sex behaviors,<sup>21</sup> and to delay, rather than hasten, the onset of sexual activity. It is also important to recognize that some sexual and reproductive health policies have been adopted in the absence of sufficient evidence or even in contradiction to the evidence. One example is the widespread promotion of abstinence-only programs, which employ prevention strategies for which evidence has not been established, while restricting the use of proven ones (Box 18.2).<sup>20</sup> In such instances, NGOs and civil-society groups, in collaboration with the research community, have a responsibility to advocate for policies founded upon evidence of impact rather than ideology. Strong advocacy and leadership are needed at the global and country level to provide clear messages about the importance of controlling sexually transmitted and other reproductive tract infections, identify the interventions and programs that work, identify the constituencies that affect resource allocation, and create multidisciplinary coalitions to advise decision-makers.<sup>2</sup>

## Program Management and Structure

To be effective, STI control programs must be tailored to the national and local epidemiological situation as well as relevant behavioral and cultural patterns. Consequently, no standard STI program will be appropriate for every country; even within a single country, an STI control program must change over time to adapt to changes in the epidemiological context and societal conditions.<sup>23</sup> Yet, even if STI programs differ in operational detail, their objectives and the requirements for an adequate management structure are inevitably similar.<sup>19</sup>

The objectives of STI control include the following:

- Interrupt the transmission of STIs;
- Prevent the development of diseases, complications, and sequelae; and
- Reduce the incidence of HIV infection.

An STI control program seeks to achieve these objectives through a management structure that delivers both communication efforts and clinical services to treat and prevent infections. Preventing

infections involves promoting sexual and reproductive health, safer sexual behavior including condom use, and assuring that high-quality, affordable male and female condoms are available. Treatment involves promoting healthcare-seeking behavior, particularly among those at increased risk of acquiring STIs, and providing accessible, acceptable and effective diagnosis and management for symptomatic and asymptomatic STI patients and their partners.<sup>10</sup>

Because the activities required for the control of HIV overlap with those required for the control of STIs, it is essential either that HIV and STI programs are fully integrated or, if independent, that there is coordinated planning and integration of selected activities. This will ensure effectiveness of both programs and will minimize duplication of effort and wastage of scarce resources. Areas for coordination or integration include care and treatment, advocacy, health education and counseling, promotion of safer sexual behavior, provision of condoms, surveillance, program evaluation and resource allocation. One way to achieve coordination is through a single manager for both programs with authority to coordinate overlapping functions. Those areas relating most specifically to STIs, such as case management, can be undertaken by a second level of management supervised by an HIV/STI manager.<sup>23</sup> The STI program should interact with other programs at the Ministry of Health and with health workers at various levels of the healthcare system, both in the public and private sectors. Collaborations should be established with medical associations, training institutions, non-governmental organizations (NGOs) and the business sector. It is particularly important to coordinate with primary healthcare, maternal and child health, and family planning programs.<sup>19</sup>

Program implementation should be decentralized as much as possible. However, there are some common functions that may be carried out by an STI management unit (e.g., in the national Ministry of Health) or otherwise coordinated to assure consistency and coherence nationally. The responsibilities that need to be coordinated at the national level include: (i) designing strategies and setting priorities; (ii) planning and supervising control activities; (iii) coordinating resources and activities within the program, and with other programs or sectors of the healthcare system, both public and private; (iv) defining case management guidelines and ensuring availability of commodities such as medications; (v) ensuring functioning of the surveillance system and identifying operational research priorities; and (vi) monitoring, supervising, evaluating, and revising the control program or planning its expansion.<sup>19</sup>

## INTEGRATION OF STI SERVICES INTO PRIMARY HEALTHCARE SYSTEMS

The experience of health programs other than STI control suggests recommendations for the introduction of STI care and prevention into general national healthcare systems:

- Integration of an STI package with a broader health structure makes sense only when the existing primary

healthcare structure functions reasonably well, providing favorable conditions for incorporating new STI services. Where a health district functions reasonably well, the chances are that integration of an STI package will go smoothly, produce results, and provide a model and motivation for other districts.

- The STI package should be as simple as possible so that it can be easily incorporated into health facilities' routine activities with minimal disruption, thus minimizing resistance from staff.
- Begin by integrating the STI prevention and care package. Once routine STI prevention and care is functioning, it is possible to move on to the second stage, with specific activities directed at partner notification and treatment, outreach to high-risk core groups, etc.
- Devise a concrete strategy to overcome likely sources of resistance that are likely to be encountered, particularly in contexts of work overload and low salaries, which may act as constraining factors. Two common types of resistance are:
  - Resistance by health workers based on fear of the unknown, prejudice and reluctance to take on further responsibilities (e.g., health education and skills development must start with healthcare workers);
  - Resistance by STI specialists based on a fear of reduced quality and loss of their power position. This can often be overcome by demonstrating the usefulness and possibilities of decentralization, as by providing specialists with a clear task description that respects their role and status in the new system (e.g., referral, quality control, training, operational research, and surveillance).
- Incorporate a system of monitoring and supervision of STI care and prevention services from the very beginning.

Any development of specialized structures such as referral laboratories or dedicated STI clinics should meet the following criteria:

- The tasks to be performed by specialized structures are essential and cannot be undertaken by existing or by upgrading existing facilities;
- No new needs should be addressed before the basic established needs are met;
- Investments in the specialized structures do not come at the expense of the support required to integrate STI care in the general health services;
- The specialized structures will exhibit comparative advantage both in the short- and long-term.

Experience suggests that, if such criteria are not met, specialized structures will divert resources meant for the strengthening of the primary healthcare network and it becomes difficult to dismantle even when proven ineffective, inefficient, or counterproductive.<sup>23</sup>

## PROGRAM PLANNING

Strategic planning is the process of defining a strategy or direction for an organization and making decisions on allocating its resources to pursue this strategy. The strategic plan orients the program over the next 3–5 years, defining goals in the specified time frame. In order to set its goals, the organization needs to assess its current situation, determine where it wants to be and how it will get there.

Planning and implementing STI control activities involve several phases: (i) conducting a situational analysis; (ii) securing political commitment; developing a national sexual and reproductive health policy including STIs and HIV; (iii) setting program priorities; (iv) designing objectives and strategies; (v) developing a work plan for implementation and support components; and (vi) mobilizing resources, and implementing a monitoring and evaluation strategy.

## Situational Analysis

A situational analysis examines the current circumstances relevant to STIs and, in particular, the factors that favor or impede STI transmission and acquisition. It thus helps to identify opportunities for change to the status quo. The analysis exercise also provides an opportunity to build partnerships across the public sector and among the public, private, and community groups in society, bringing a wide range of people, skills, and resources into the national response.

During a country's first situational analysis exercise, the government should try to involve as many *key* stakeholders as possible, not only to increase diversity and expertise, but also to create a sense of ownership among involved agencies. This involvement is also crucial for resource mobilization. Bilateral donors or international NGOs are often keen to participate in the different phases of the strategic planning process. It is also important to involve the community and representatives from the most affected populations such as people living with HIV, sex workers, and men who have sex with men.<sup>24</sup>

The situational analysis should include a description of STI epidemiology, existing services, available resources, and influential factors (political, cultural, legal, and other) (Box 18.3). The outcome therefore is not a mere description of the STI epidemiological status in the country; it is a diagnosis of the major underlying determinants and an identification of groups or populations most vulnerable to STIs. In the process, the team also pinpoints the major obstacles to, and potential opportunities for, improving the situation and strengthening the response. It thus paves the way for developing the most appropriate strategies. Box 18.3 lists the main questions to be addressed in the situational analysis.

## Political Commitment

However good the available technologies and interventions, they will be of no sustainable benefit to the population without the

**Box 18.3** STI Situational Analysis**Objective:**

To understand the current STI status and what can be done to improve it.

**Main Questions:**

- What is the STI situation in the country or a particular area?
  - Epidemiology and clinical syndromes, STI pathogens and their antibiotic sensitivities;
  - Type and size of populations at greatest risk.
- What major factors and risk behaviors are associated with STIs?
- Which are the existing services, public sector and private sector, including physicians, other healthcare workers providing STI services, pharmacies and unqualified healthcare providers?
- What is the STI healthcare-seeking behavior among the general population and high-risk and vulnerable groups?
- Which political, legal, and social factors that may influence the national (or local) program?
  - Positive or negative political commitment.
  - Legal constraints:
    - Registration of sex workers and/or establishments;
    - Availability of antibiotics without prescription.
- What are the priority areas that need to be addressed now and in the short and medium term?
- What obstacles are there to improvement or change in priority areas?
- What opportunities are there for positive changes?
- What are the available resources:
  - Allocation of funds from the Ministry of Health (or local authority);
  - Available personnel;
  - Infrastructure, equipment, materials, consumables;
  - Availability of and funding for drugs;
  - Resources for study, operational research, curriculum development (university clinic, medical schools, social studies and educational institutions, etc.);
  - Actual/potential additional resources (such as international agencies, donors, NGOs);
  - Availability and commitment of other healthcare programs/services that can deliver STI care (such as reproductive health programs).

**Means:**

- Key informant interviews:
  - Ministry, district, and local officials;
  - Healthcare providers;
  - NGO staff;
  - General and target populations.
- Documents:
  - Reports, laws, and regulations;
  - HIV plans;
  - Health facility and laboratory records;
  - Publications and internal reports from local and national government offices, NGOs, donors and neighboring countries (areas);
  - Visits and observation.

Note: Adapted from Lamprey PR, Gayle HD, eds. *HIV/AIDS Prevention Care Resource-Constrained Settings, A Handbook for the Design and Management of Programs*. 1st Ed. Arlington, VA; 2001.

political will and resources to continue their implementation. In most countries, it is difficult to promote safer sexual behaviors and introduce sex education into school curricula without the due level of political commitment. Advocacy must occur at both the country and global levels to put STI control high on the national

health agenda. Furthermore, strong leadership supported by civil society, a clear vision, messages, strategies, and interventions with a solid science base is required to inspire action. At the country level, advocacy should promote enabling policies and legislation. Existing regulations and legislation should be reviewed to assess their utility and contribution to prevention and care policy, goals and objectives relating to STIs. Consideration should be given to reforming policies and legislation that obstruct the goals of prevention and care.<sup>10</sup> As discussed above, a national reproductive and sexual health policy is essential in each country.

### Select Program Priorities

The situational analysis identifies the most important STI determinants and weaknesses in the response, and recommends focus areas for a new strategic plan. Through situational analysis, each country will identify its own priority areas for action. Countries must implement or scale up the provision of care for those with STI through activities for which there is sufficient knowledge and evidence of impact and feasibility. The World Health Organization drafted a Global Strategy for STI Control that outlines a series of activities that may serve as guidance. Table 18.1 describes these activities, together with indicators and national targets.<sup>3</sup> Priority 1 activities are interventions that have been implemented in many places with modest additional human and financial resources. Priority 2 activities are interventions that may require substantial human and financial resources, and plans should be made for stepwise implementation as resources become available.

### Design Objectives and Strategies

The general objectives of an STI control program delineate the program's expected achievements. Specific objectives detail accomplishments for a given period of time, and steps toward achieving the program's larger objectives. They should be formulated including the expected outcomes, target populations and geographic areas or socioeconomic levels, and the timeframe for reaching the stated outcomes. The target is usually expressed as a proportion of the population for which a specific outcome is expected. For example: 90% of STI patients attending public facilities in the capital city will be managed according to national diagnostic and treatment guidelines by the end of year two.

A set of activities undertaken to meet a specific objective constitutes a strategy. One or more strategies may be implemented to meet an objective. The relationship between specific objectives, strategies and activities is illustrated in Box 18.4, while examples of activities, indicators and targets are listed in Table 18.1.

### Designing Strategies

At a minimum, strategies need to be designed for the following program components:

1. Behavior change strategies to promote safer sexual behavior, consistent and correct condom use, and appropriate

### Box 18.4 Example of Objectives, Strategies, and Activities for STI Program Priorities

#### Objective

By the end of the year 3500 female sex workers and 3000 men who have sex with men in the capital city will have been reached with an evidence-based behavioral change intervention for high-risk groups.

#### Strategy

Network based behavioral change intervention

#### Activities

- Estimate the size of the population of female sex workers and men who have sex with men in the capital city.
- Organize a prevention committee with organizations working on prevention with high-risk groups.
- Develop access to target groups through key members.
- Develop a work plan to coordinate activities.
- Train health providers and peer educators in outreach activities.
- Develop a reporting mechanism.
- Monitor activities.

healthcare-seeking behavior – including efforts directed at reducing stigma and discrimination;

2. Delivery of services for management of STI patients and their partners;
3. Condom programming.

These components must be implemented in a coordinated fashion. For example, if the behavioral change communication recommends early treatment of STIs, then such services should be available. Similarly, if the use of condoms is promoted, they should be accessible. These and other components of an STI program are discussed in more detail in the next section of this chapter.

### Work Plan for Implementation and Support Components

After defining program priorities and strategies, the program manager must prepare a plan for implementing control activities. Close coordination with the essential drugs program is a key to ensuring availability of appropriate STI drugs at primary healthcare facilities. If the strategic plan involves providing STI case management for women through maternal and child health, family planning and antenatal clinics, these programs should be involved early in the planning process. Available financial, human and physical resources must be considered when planning STI control to avoid constraints imposed by resource shortages. For example, limited funds for training staff in syndromic management will mean that program activities cannot be implemented countrywide. It is often necessary to adopt a phased approach to program implementation. For example, a program could initially develop interventions in one or more urban areas where high-risk behavior is common and STI incidence is high. Simultaneously, additional research on the etiology of STI syndromes and on antibiotic susceptibility patterns could begin. In a later phase, services could be expanded to other urban settings and to rural areas as well. Preparation of

a step-by-step work plan with a realistic timetable and budget is a crucial step in program planning.<sup>19</sup>

The following support components are essential to developing and implementing an STI control program and should be included in the detailed work plan:

- Guidelines;
- Training;
- Clinical mentoring and supportive supervision;
- Logistics (including drugs and condoms);
- Laboratory services;
- Research;
- Surveillance;
- Monitoring and evaluation for the program.

These components are discussed in more detail in other sections of this chapter.

### Mobilize Resources

In order to implement the strategy, a mechanism to mobilize additional resources will likely be needed. For developing or resource-limited countries, various sources can be explored. For example, countries may take advantage of the opportunity to develop proposals for the Global Fund to Fight AIDS, Tuberculosis and Malaria that include strategies for STI control. At the global level, international agencies should intensify discussions on funding for STI control through such mechanisms. There are also other opportunities, such as foundations interested in STI control in general or for specific populations. At the national level, advocacy strategies for adequate resource allocation for programming for the prevention and control of STIs should be developed.<sup>25</sup>

### Essential Components of an STI Control Strategy

The three main objectives of an STI control program (interruption of transmission of STIs, prevent development of disease, reduce incidence of HIV), along with the three core intervention strategies (behavior change, management of STIs, condom programming), have been discussed in the previous section of this chapter. Additional strategies that may be considered include control of congenital syphilis and treatment and prevention of neonatal conjunctivitis. For effective implementation of these strategies, a number of support activities need to be developed. These include development of guidelines, training, supervision, logistics, laboratory services, research, surveillance, and program monitoring and evaluation. Other support components that are usually outside the direct influence of an STI control program consist of commodities procurement and distribution systems for drugs, condoms and laboratory supplies; a health education unit that supplements and reinforces in-clinic messages for behavioral change and appropriate healthcare-seeking behavior and a health statistics unit to process and analyze surveillance data.

National guidelines for patient management and STI treatment must be developed and widely disseminated. This will facilitate the development of training materials and programs. Specification

**Table 18.1:** Summary of Actionable Interventions for Immediate Implementation

Priority 1 activities	Indicators	National targets
1. Scale-up of services for diagnosis and treatment of STIs (use syndromic management where diagnostic resources are limited)	1(a). Proportion of primary point-of-care sites providing comprehensive case management for symptomatic infections 1(b). Proportion of patients with STIs at selected health facilities who are appropriately diagnosed, treated and counseled according to national guidelines	1(a). 90% of primary point-of-care sites provide comprehensive care for people with STIs by 2015 1(b). By 2015, 90% of women and men with STIs at healthcare facilities are appropriately diagnosed, treated, and counseled
2. Control congenital syphilis as a step towards elimination	2(a). Proportion of pregnant women aged 15–24 years attending antenatal clinics that are screened for syphilis 2(b). Proportion of pregnant women aged 15–24 years attending antenatal clinics seropositive for syphilis that are adequately treated	2(a). More than 90% of first-time antenatal clinic attendees aged 15–24 years screened for syphilis 2(b). More than 90% of women seropositive for syphilis treated adequately by 2015
3. Scale up STI prevention strategies and programs for HIV-positive persons	3. Proportion of primary point-of-care sites that provide effective care to HIV-positive patients with STIs including advice on condom use and partner notification	3(a). Strategies and guidelines on interventions for HIV-positive patients with STIs in place by 2015 3(b). 90% of primary point-of-care sites provide effective care to HIV-infected patients with STIs
4. Upgrade surveillance of STIs within the context of second-generation HIV surveillance	4(a). Number of prevalence studies regularly conducted (at sentinel sites or in sentinel populations) every 3 to 5 years 4(b). Annual incidence of reported STIs (syndromic or etiological reporting)	4(a). At least two rounds of prevalence surveys conducted by 2015 4(b). Routine reporting of STIs established and sustained over at least 5 consecutive years by 2015
5. Control bacterial genital ulcer disease	5(a). Proportion of confirmed cases of bacterial etiology among patients with genital ulcerative diseases 5(b). Percentage of pregnant women aged 15–24 years attending antenatal clinics with a positive serology for syphilis	5(a). Zero cases of chancroid identified in patients with genital ulcer disease by 2015. 5(b). Less than 2% of positive syphilis serology among antenatal clinic attendees aged 15–24 years
6. Implement targeted interventions in high-risk and vulnerable populations	6(a). Health needs identified and national plans for control of STIs, including HIV, for key high-risk and vulnerable populations developed and implemented 6(b). Proportion of young people (aged 15–24 years) with infections that were detected during diagnostic testing for STIs	6(a). By 2015, health needs, policies, legislation, and regulations reviewed; plans in place and appropriately selected country-specific targeted interventions implemented 6(b). At least two rounds of prevalence surveys conducted among groups with high-risk behavior and among young people by 2015
Priority 2 activities	Indicators	National targets
7. Implement age-appropriate comprehensive sexual health education and services	7. Percentage of schools with at least one teacher who can provide life-skills-based education about prevention of HIV and other STIs	7(a). Review of policies and development of age appropriate training and information materials for schools completed by 2015 7(b). Increased number of teachers trained in participatory life-skills-based HIV education that includes other STIs by 2015
8. Promote partner treatment and prevention of re-infection.	8. Proportion of patients with STIs whose partner(s) are referred for treatment	8(a). Plans and support materials for partner notification developed, and healthcare provider training in place by 2015 8(b). The proportion of patients who bring in, or provide treatment to, their partner(s) doubled by 2015
9. Support roll-out of effective vaccines (against hepatitis B and human papillomavirus and, potentially, herpes simplex virus type 2 infections)	9(a). Policy and plans for universal immunization against hepatitis B 9(b). Plans and policy reviews and strategies for use of human papillomavirus and potential herpes simplex virus type 2 vaccines	9(a). Plans in place regarding immunization against hepatitis B and human papillomavirus infection by 2015 9(b). Pilot immunization programs initiated and scaling up in progress by 2015
10. Facilitate development and implementation of universal opt-out voluntary counseling and testing for HIV among patients with STIs	10. Proportion of patients assessed for STIs who are routinely counseled and offered confidential testing for HIV	10(a). HIV testing and counseling available in all settings providing care for people with STIs by 2015 10(b). The proportion of patients with STIs who receive voluntary counseling and testing for HIV doubled

Note: Adapted from World Health Organization. Global strategy for the prevention and control of sexually transmitted infections: 2006–2015: breaking the chain of transmission. Geneva, Switzerland; 2007.

of selected recommended essential STI treatments will simplify STI drug logistics and monitoring of antimicrobial sensitivity. Obtaining broad consensus is an essential aspect of national policy and guidelines development.

We now turn to the core elements of an STI control program strategy in detail.

## BEHAVIOR CHANGE

An effective response to the spread of STI starts with accurate and explicit information on safer sex, including correct and consistent use of male and female condoms, delay in onset of sexual activity, keeping to one, ideally uninfected, sexual partner or reducing the number of sexual partners. A behavior-change strategy should be an integral component of prevention efforts and incorporated into care and support activities. It can increase knowledge of HIV and STI prevention, stimulate dialogue within the community, promote essential changes in attitudes, reduce stigmatization and discrimination, create demand for information and healthcare services, advocate for appropriate policies and laws and improve skills and self-esteem.<sup>26</sup>

When choosing the communication channels for sexual behavior-change messages, it is important to know which can most effectively reach the target population. One successful channel for targeted interventions is through peer educators and opinion leaders. Informational sessions on health through institutional or interpersonal networks, group discussions, or other one-to-one approaches have also been used. Age-appropriate school-based programs help in reaching young people, but for the out-of-school population, other channels, such as peer education, are necessary. Whatever channel of communication is chosen, it is important to use language that is well understood by the target population. Care should be taken that the messages are sensitive to gender and culture and that they do not reinforce any existing norms driving the spread of STIs.<sup>3</sup>

Health education about STIs and counseling of both infected and uninfected people, inclusive for HIV testing, should be an integral part of any health service, as the counseling process creates motivation to change sexual behavior in both infected and uninfected individuals. Education and counseling messages should also highlight the need for sexual partners to be informed and treated properly to avoid repeated infections.<sup>3,19,27</sup>

Development and strengthening the provision of STI care needs to be accompanied by the education of potential service users on the availability and advantages of the services. This should take into account the reasons why many individuals fail to seek early treatment. Some may not seek treatment for the STI, but receive a diagnosis when they attend a medical service for another unrelated condition. Innovative strategies to increase demand for high-quality services should be used. These may include: market-oriented methods for raising consumer awareness of correct, high-quality treatment to be expected from care providers; education for youth in- and out-of-school; education

in health facility waiting areas; education as part of the STI consultation; and peer education initiatives in the community. This approach relies on appropriate changes in the supply of healthcare services to meet increasing demand. Creating high expectations that are not met can be detrimental to continuing service utilization.

## STI CASE MANAGEMENT

Prompt and effective STI treatment is an essential component of STI control. Comprehensive management involves prompt diagnosis and treatment, together with education and counseling of patients on treatment compliance and risk reduction, partner notification and provision of condoms. Several factors interfere with effective STI case management. These include a large number of asymptomatic infections in women, inadequately trained and judgmental health providers, the lack of appropriate diagnostic tests and the lack of effective drugs.

## Syndromic Management

The greatest deficiency in individual case management in resource-poor settings is the scarcity of affordable and accurate diagnostic tests. Syndromic management remains the core intervention in the WHO strategy for delivering prevention and care for people with STIs in resource-poor settings where laboratory testing is not available.<sup>3</sup> Syndromic management involves the use of flowcharts to help healthcare workers identify groups of symptoms and easily recognizable signs (syndromes) and guide treatment to cover the most probable causes of the syndrome.<sup>22</sup> Syndromic treatment of patients at the first visit avoids loss to follow-up and provides an opportunity for education, advice on sexual behavior, promotion or provision of condoms and partner notification. The syndromic approach, which can be used at all levels of healthcare,<sup>28</sup> treats mixed infections, and prospective studies provide some evidence of effectiveness in the management of symptomatic urethritis and epididymitis in men and genital ulcer disease in both women and men.<sup>29</sup> In recent years, HSV type 2 has emerged as the most common cause of genital ulcer disease.<sup>30</sup> WHO guidelines now recommend incorporation of acyclovir into the syndromic treatment package for genital ulcers under specific circumstances.<sup>22</sup>

The syndromic flowchart for the management of vaginal discharge is inadequate for controlling STIs in women because this symptom is a poor proxy for endocervical chlamydia and gonorrhea.<sup>31</sup> Sensitivity and specificity remain low even when supplemented by speculum examination and risk assessment.<sup>29,32</sup> Even in settings where the prevalence of endocervical infections is above 15%, fewer than one in three women diagnosed syndromically will have an STI.<sup>28</sup> Since syndromic management is not appropriate for cervical infections, the use of flowcharts for vaginal discharge has been suggested to provide treatment for vaginal STI trichomoniasis and endogenous reproductive tract infections (bacterial vaginosis and candidiasis).<sup>28,32</sup>

### Box 18.5 Problems with the Management, Use, and Distribution of Drugs for STI Treatment

- Available drugs are ineffective due to the development of antimicrobial resistance.
- Effective drugs for STIs are available only in the private sector (subject to additional taxes), and thus unaffordable to a vast majority of STI patients.
- Effective drugs are not included on the national essential drug lists.
- Healthcare providers continue to prescribe drugs to which the organisms have developed resistance despite the availability of alternatives.
- Pharmacists sell drugs over the counter in doses lower than those recommended when the customer cannot afford to buy the full, recommended dose.
- Out-of-date, counterfeit or inactive drugs.
- Drug vendors sell drugs that are ineffective and/or inadequate.
- Practices that result in ineffective therapy include polypharmacy, whereby several antibiotics with overlapping effects as well as unnecessary creams or ointments are prescribed, resulting in increased cost to the patient as well as unreasonable demands on the patient's ability to remember and comply with instructions.
- Inadequate or nonexistent patient education regarding the prescribed drug, and instructions about how, when and for how long to take it, result in poor patient compliance with the required treatment.
- Patients' difficulty in remembering to take several doses of a pill a day for several days; providers should try to prescribe the drug that requires the fewest doses for the shortest possible period of time and with the fewest side effects.

## Drugs

The availability of effective drugs is crucial for successful STI management, yet it is a problem in many countries. Box 18.5 details several major problems related to the availability of effective drugs that, unless resolved, may reduce the effectiveness of STI prevention and control efforts. The evolution of antimicrobial resistance has made the treatment of gonorrhea and chancroid more complicated and expensive.<sup>33,34</sup> A monitoring system for detecting antimicrobial resistant STI strains and treatment failures is therefore fundamental to procuring more effective drugs and updating providers about current recommendations.<sup>33,35,36</sup>

## Partner Management

Partner notification aims to prevent onward transmission of infection and, if successful, can also prevent re-infection of the index case. Partner notification is a process that includes informing sexual partners of their infection, administering epidemiological treatment and providing advice about the prevention of future infection.<sup>27</sup> Partners can be informed by the patient (patient referral), the health professional (provider referral), or by the health professional if the patient has not done so within an agreed time (contract or conditional referral). In practice, patient referral is the most commonly used, and is the preferred method.<sup>37</sup> A range of partner notification approaches can increase the numbers of sexual partners treated for gonorrhea, chlamydia, syphilis, HIV, trichomoniasis, and STI syndromes, though only a proxy outcome that assumes that partner treatment prevents onward

spread.<sup>37–40</sup> Recent trials have shown that the risk of re-infection or persistent infection in index cases can also be reduced. When compared with basic patient referral, four trials in which index cases received antibiotics or prescriptions to give directly to their partner(s) (patient-delivered partner therapy) showed a reduced risk of reinfection with gonorrhea or chlamydia.<sup>40</sup> For transmission to be interrupted in the population, enough partners of index cases, and their partners, have to be traced and treated for the intervention to have an effect.<sup>41</sup>

## Periodic Presumptive Treatment

*Presumptive treatment* is defined as one-time treatment for a presumed infection in a person, or a group of people, at high risk of infection. Presumptive treatment for STIs is often given at regular, repeated intervals, in which case it is known as *periodic presumptive treatment*.<sup>42</sup> In theory, this approach should reach a greater proportion of people with STIs than treating only those with symptoms, and avoids the costs of diagnostic tests. The interval between treatments must, however, be short enough to deal with reinfection.<sup>43</sup> In Rakai, Uganda, treatment at 10-month intervals had little effect on transmission in the general population, with a reduction in long-term syphilis reactivity and trichomonal infections but no effect on gonorrhea, chlamydia, bacterial vaginosis, or reports of urethral discharge, vaginal discharge, or genital ulcers.<sup>44</sup> The reductions in infection were outweighed by the operational requirements of implementation. Presumptive treatment has been recommended as a temporary strategy to reduce prevalence as part of a package of services in populations known to have very high prevalence of STIs while other curative and preventive services are being strengthened. In female sex workers given monthly single-dose antibiotics in Benin, Ghana,<sup>42</sup> and Kenya,<sup>45</sup> however, only one of three randomized controlled trials, in Kenya, showed a reduction in chlamydia and gonorrhea. The intervention had no effect on HIV acquisition. A program administering periodic presumptive treatment to female sex workers based within geographically self-contained mining communities in South Africa,<sup>46</sup> for instance, found that prevalences of gonococcal and chlamydial infections declined in the women following the intervention. Among the miners in the area, both the rates of genital ulcer disease and urethral discharge also fell sharply suggesting a flow-on population impact in a client group whom did not receive any intervention. Chancroid, which had been the leading genital ulcer among both miners and sex workers at the beginning of the program, was effectively eliminated. Periodic presumptive treatment has not been assessed in other groups—e.g., men who have sex with men, male sex workers, clients of sex workers.

## PROMOTION OF CONDOMS AND OTHER BARRIER METHODS

The male latex condom is the single most efficient technology available to reduce the sexual transmission of HIV and other STIs. Although the female condom is effective and safe, use remains limited by its relatively high cost and variable acceptability among both healthcare providers and potential users.

Male and female condoms and water-based lubricants are a key component of comprehensive prevention strategies, and all should be made readily and consistently available to all those who need them in order to reduce risks of sexual exposure to STIs including HIV. Once procured, condoms should be promoted and distributed through both the public and private sectors, in clinical and non-clinical settings. Maternal and child health as well as family planning clinics are good additional outlets for condom distribution, increasing accessibility to women who could be at risk of STIs. A recent meta-analysis has shown that structural-level interventions aiming to increase the availability, accessibility, and acceptability of condoms are effective in increasing condom use, condom acquisition or condom carrying, promoting delayed sexual initiation or abstinence among youth, and reducing incident STIs.<sup>47</sup> Condom distribution programs were also efficacious in increasing condom use among a wide range of populations including youth, sex workers, adult males, STI clinic patients, and populations in high-risk areas. Program managers interested in implementing a condom distribution strategy should consider the following elements<sup>48</sup>:

- Provide condoms free-of-charge.
- Conduct wide-scale distribution.
- Implement a social marketing campaign to promote condom use (by increasing awareness of condom benefits and normalizing condom use within communities).
- Conduct both promotion and distribution activities at the individual, organizational, and community levels.
- Target: (i) individuals at high risk, (ii) venues frequented by high-risk individuals, (iii) communities at greater risk for HIV infection, especially those marginalized by social, economic or other structural conditions, or (iv) the general population within jurisdictions with high HIV incidence.
- Supplement the condom distribution program with more intense risk-reduction interventions or other prevention or health services for individuals at highest risk. Integrate condom distribution program activities with other community-level intervention approaches to promote condom use and other risk reduction behaviors.
- Conduct community-wide mobilization efforts to support and encourage condom use and address misleading anti-condom messaging by moralizing influential community leaders.

It is also important when launching a condom distribution program to identify and engage appropriate community partners, identify obstacles in reaching members of vulnerable populations and strategies to overcome them. There should be an evaluation of program costs to determine the largest feasible scale. Laws and policies that may support or hinder the program should be identified.

Developing linkages to NGO-managed community-based distribution of condoms and condom social marketing programs can expand the condom promotion efforts. Condom social marketing programs combine vastly expanded condom accessibility with consumer-friendly promotion. These programs sell brand-name condoms through a wide variety of sales points,

including traditional chemist and small retail shops and a myriad of nontraditional outlets, such as bars, hotels, restaurants, market stalls, sidewalk vendors, brothels, kiosks, taxis, and boat launches. Programs around the world have demonstrated that making condoms available at an affordable price in places convenient to users can result in staggering condom sales.<sup>19</sup> In addition to greatly expanding access to condoms through traditional and nontraditional sales outlets, condom social marketing programs have demonstrated a unique ability to diminish social taboos surrounding condom use through their innovative use of both conventional and nonconventional advertising, comedy, street theater, promotional items, and other techniques for changing attitudes. These strategies have served to reposition condoms in the minds of members of target audiences. As a result, the condom is no longer viewed as foreign, sterile medical technology, but rather as a simple consumer product that is easy to use, effective, and increasingly popular.<sup>49</sup>

Other barrier methods such as the diaphragm and microbicides have showed mixed results. A randomized controlled trial failed to show any protection with diaphragms for HIV transmission or STIs.<sup>50</sup> However, among consistent diaphragm users there was some protection for gonorrhea infection.<sup>51</sup> Recent studies evaluating microbicides have shown promising results with some protection of microbicides against HIV although the mechanisms applied are unlikely to prevent bacterial STIs.<sup>52</sup>

## CONTROL OF CONGENITAL SYPHILIS AND NEONATAL CONJUNCTIVITIS

When STIs affect pregnant women, fetuses and newborn infants can also become infected, potentially leading to infant morbidity and mortality. Antenatal screening programs are good examples of interventions that use efficacious single interventions—e.g., diagnostic tests and antibiotics—but for which effectiveness in prevention of transmission is dependent on delivering them in an organized, sustainable way, and in a receptive environment. Intramuscular penicillin for pregnant women with syphilis is effective in preventing congenital syphilis.<sup>53</sup> Because of the high prevalence in developing countries of gonorrhea and chlamydial infections, and the consequent risk of newborn children developing gonococcal or chlamydial ophthalmia, routine prophylactic treatment for such ophthalmia at birth is recommended.<sup>37</sup>

## INTERVENTIONS FOCUSED ON CORE GROUPS

In some geographical settings, rates of STIs in the general population are high, while in others, high rates are confined to specific population groups. Exercises that map infection levels, sexual behaviors (e.g., number of sexual partners and rates of partner change), preventive behaviors (e.g., correct and consistent condom use), and health-related behaviors (e.g., STI treatment-seeking) in population groups with high rates of infection and in vulnerable groups, as well as in the general population, provide valuable information on the transmission

**Box 18.6****Populations at Highest Risk of HIV and Other STIs in Different Settings**

- Sex workers (female, male, and transgendered) and their clients have sex with their regular partners.
- Mobile populations such as long-distance truck drivers, fishermen, seafarers, and migrant workers at increased risk of infection primarily because of their mobility and high-risk sexual contacts.
- Men who have sex with men and transgender women who have multiple sexual partners and engage in unprotected anal intercourse.
- Men who have sex with men as well as women.
- Substance users, especially those who also sell or exchange sex to support their habit or who have sex with non-users.
- Incarcerated persons, especially juveniles.
- External, internal refugees and displaced persons.
- Members of the uniformed services, including military and police.
- Tourists, especially recreational sex tourists.
- Women or men who experience sexual and gender-based violence.
- Children and young people on the street, and those who are abused or are orphans.
- Adolescents at special risk of STIs including HIV, due to lack of the information, skills, healthcare and support needed while going through sexual development.

dynamics and help to determine which interventions for control would be most successful. Targeted interventions should be prioritized according to the needs, feasibility, and availability of resources. The populations vary among regions and countries. Those frequently observed to be in need of targeted interventions are listed in Box 18.6.

## OTHER SUPPORT COMPONENTS

### Supervision

Supervision is a two-way process by which the manager observes and keeps in touch with events, which enables the staff to give feedback, discuss and be reassured and supported. Regular supervisory and monitoring visits to health facilities are an important component of ensuring the continued provision of good quality care and sustaining provider morale and motivation. Such supervisory visits need not be confined to the public sector. They can be adapted to the private sector to maintain quality, provide continuing education, and serve as a means of collaboration between the private and the public sectors.<sup>3</sup> Supervisory visits need to adopt a facilitation process in order not to be a threat to the healthcare providers or other staff, but rather a source of encouragement, and a means of updating healthcare providers and constantly improving quality of care. A supervisory program also needs to be contemplated for outreach workers who are the key to improve access to hard-to-reach populations. Training of supervisors is important, so that they can reorient their skills to being supportive rather than judgemental and fault-finding. Laboratories providing STI support also benefit from supervision of logistics, services, and laboratory investigation.

### Training

Training is a key component of any STI control program. Program managers at the national and local levels need training in the planning and management of STI programs. This involves the development of skills in situational assessment, prioritization and resource allocation, a good understanding of public health measures for STI control and the need to collaborate with and involve different partners in the public and private sectors. Service providers including outreach workers need to be trained in effective case management, education and communication on sex, sexuality, STI and HIV, prevention, condom use, treatment adherence, partner notification, and the development of nonjudgmental and open attitudes. Laboratory technicians may require refresher training in the use of STI diagnostics.

For training to be effective and achieve optimal use of limited resources, training must be needs-based, skills-oriented and targeted to the specific audience. Thus, the skills required by a particular group of healthcare workers or program managers should be carefully defined and training needs carefully assessed.

### Laboratory Services

Depending on the size of the country, it is important that one or more laboratories be prepared to conduct the essential epidemiological and microbiological research necessary for surveillance efforts. Where possible, laboratory tests with a short turnaround time should be available to assist in treatment decisions, particularly in cases that are unresponsive to the first course of treatment. The laboratory can play an essential role in epidemiological and microbiological surveys, antimicrobial susceptibility studies and in the validation of treatment and management approaches. Laboratories should be established and strengthened at national and regional levels and, where feasible, laboratory support can be established at the local level. Such a network of laboratories can work together to strengthen services. To be cost-effective, the network should identify clear roles and areas of responsibility as recommended in Box 18.7.

### Monitoring and Evaluation

It is easy to understand the imperative of assuring that funded initiatives work as expected and succeed in achieving the intended results toward STI control and quality-of-life improvements. Even when resources are plentiful, good program functioning and impact are desirable. Monitoring and evaluation (M&E) systems provide data and analysis regarding program functioning and results to guide decision-making and are an essential component of all health services and interventions. Yet, despite important achievements, M&E continues to be regarded as one of the weakest components of STI programming, so that evidence to guide programmatic decisions is often unavailable or inadequate. The Global Fund to Fight AIDS, Tuberculosis and Malaria recommends that programs spend 5% to 10% of funds on M&E systems.<sup>54</sup> M&E of STI activities should address the coverage,

### Box 18.7 Laboratory Roles and Responsibilities at Different Levels of the Health System

#### National level

- Conducting epidemiological, sentinel, and etiological surveys to monitor disease trends and effectiveness of interventions.
- Validating and adapting flowcharts for recommendations and guidelines for syndromic management.
- Establishing national proficiency and quality control systems for the laboratory diagnosis of STIs.
- Providing training workshops for laboratory diagnosis of STIs.
- Evaluating performance and cost-effectiveness of new diagnostic tests.
- Collating data on antimicrobial susceptibility patterns and making recommendations.
- At referral centers, establishing diagnoses in cases that fail syndromic case management and for medico-legal purposes (e.g., rape or sexual abuse).
- Initiating or strengthening screening programs for asymptomatic gonococcal and chlamydial infections, especially among target populations such as sexually active young women and men.

#### Regional level

- Conducting etiological surveys to monitor disease trends and effectiveness of interventions.
- Monitoring patterns of antimicrobial susceptibility.
- Supporting regional proficiency and quality control systems for the laboratory diagnosis of STIs.
- Providing training workshops for laboratory diagnosis of STIs.

#### Local level

- Supporting sentinel surveys.
- Providing routine serological testing for syphilis in pregnant women.
- At referral centers, establishing diagnoses in cases that fail syndromic case management.

**Note:** Adapted from World Health Organization. Global strategy for the prevention and control of sexually transmitted diseases: 2006-2015: breaking the chain of transmission. Geneva, Switzerland: World Health Organization; 2006.

quality and effectiveness of all STI services provided, including laboratory services. Monitoring and evaluation processes for STI programs are further discussed in Chapter 20.

## Operational Research

Closely related to evaluation is operations or operational research (distinct from the mathematical science concerned with optimal decision-making of the same name).<sup>55</sup> In M&E, operational research refers to any research undertaken to understand and improve program implementation or to identify new areas where interventions are needed. Notably, decision science tools from classical operational research, such as cost-effectiveness analysis, may form a part of M&E efforts. The Global Fund to Fight AIDS, Tuberculosis and Malaria defines operational research as follows<sup>56</sup>:

*“Any research producing practically-usable knowledge (evidence, findings, information, etc.) which can improve program implementation (e.g., effectiveness, efficiency, quality, access, scale-up, sustainability) regardless of the type of research (design, methodology, approach) falls within the boundaries of operations research.”*

As defined above, process and impact evaluation would be considered a kind of operational research. Operational research may involve embedding trials or studies within projects to fine-tune implementation<sup>57</sup> and may use rapid assessment or social science research tools, such as direct observation, interviews, focus groups or surveys of staff or program participants. For example, operational research efforts in Cambodia sought to better understand TB management in the private sector through interviews with doctors, pharmacists, pharmacy staff and patients, as well as using “mystery clients” posing as patients. In this instance, the research identified areas in need of improvement for TB management in private sector facilities.<sup>54</sup>

## Surveillance

Data from STI surveillance systems, correctly implemented and used, serve a number of public health functions:

- To detect cases and case clusters to guide interventions where infection is occurring;
- To support evaluations of determinants of infection and impact;
- To determine the need for public health interventions;
- To monitor the effectiveness of prevention and control measures;
- To develop hypotheses to guide studies of risk factors and causes of infection and disease progression.

Additionally, surveillance systems should place special emphasis on detecting and understanding new infections and behavioral patterns to anticipate how STI epidemics may evolve over time.<sup>58</sup>

*Second-Generation Surveillance* is concerned with both biological (e.g., prevalence and incidence) and behavioral information to characterize and track risk behaviors and contextual determinants that elevate vulnerability to infection (e.g., migration or refugee status leading to increased risk of sexual assault). Second-generation surveillance has primarily an HIV focus but is also relevant for surveillance of other STIs. WHO-UNAIDS guidelines for *Second-Generation Surveillance* in HIV recommend several surveillance components: routine surveillance based on case reporting of HIV, AIDS, and other STIs; behavioral and biological surveillance studies in most-at-risk populations; population size estimation of most-at-risk populations to support projections; and regular analysis to maximize data utilization.<sup>59</sup> The frequency and extent to which these components are required will depend on the type of epidemic.

Surveillance studies in most-at-risk populations for HIV increasingly incorporate estimation of HIV incidence, although methodological problems exist,<sup>60</sup> as well as genotyping to estimate levels of primary resistance of HIV to antiretroviral medications. Surveillance studies that use probability sampling techniques in most-at-risk populations may also incorporate estimation of population size at lower cost compared to size estimation outside the context of a surveillance study.<sup>61</sup> Generally, studies for surveillance purposes should assure adequate representativeness

of target populations to enable statistically valid comparisons between geographic locations and over time.

## Considerations for Scaling Up STI Programs

A common challenge to STI programs in achieving a significant health impact is that of “scaling up”, or dramatically expanding services so that they are universally available.<sup>62</sup> The challenge of scale-up however, is not just one of funding levels. Understanding why efforts to make proven, effective health strategies—such as routine antenatal screening to prevent congenital syphilis—widely available often fail is a nebulous affair, although common reasons include limited health systems capacity, political will and cultural acceptability. A conceptual framework for understanding constraints to scale-up was put forward by the Commission on Macroeconomics and Health, which was convened by the World Health Organization, and concerned primarily with “priority” health interventions that it considered promising toward meeting economic development and equity objectives, including those targeting HIV and other STIs.<sup>62</sup> Constraints were classified according to organizational-institutional level and their likely responsiveness to increased funding. The Commission’s work proposes that those constraints deemed most amenable to improvement through additional funds are those that operate at the community and household levels (lack of demand for services and barriers to utilization), health services level (staffing, management and supervision, supplies, equipment and health infrastructure) and some at the cross-cutting public policy level (communication and transport infrastructure). Constraints seen as largely unchangeable or requiring strategies beyond resources alone occurred at the level of policies, management, and national context (e.g., government bureaucracy and corruption, political stability and security, political will and geographic disposition to disease).<sup>63</sup>

### Box 18.8

#### Strategies for Improving Health System Performance for Scale-up

- Community participation approaches that are highly collaborative.
- Quality assurance, especially via participatory approaches.
- Strengthening management capacity.
- Training programs provided they are:
  - Regular rather than intermittent;
  - Adaptive to changes in the health situation;
  - Linked with supervision.
- Integrated drug policies, including selection, procurement, distribution, prescription and patient education.
- Promoting health services in underserved groups.
- Innovatively addressing bureaucratic barriers.
- Focused objectives, monitoring systems, and good technical design.

**Note:** Based on Seshadri S. Constraints to scaling-up health programmes: a comparative study of two Indian states. *Journal of International Development* 2003;15:101–14; and Wyss K, Moto D, Callewaert B. Constraints to scaling-up health related interventions: the case of Chad, Central Africa. *Journal of International Development* 2003;15:87–100.

Strategies that tend to be effective in overcoming common barriers to scale-up were identified in a review<sup>3</sup> and three country case studies applying the constraints framework, which build on the Commission’s work (Box 18.8).<sup>64–66</sup> Although what works inevitably depends upon the particular intervention and local context, a finding uniform across programs examined is the importance of highly collaborative strategies that utilize community participation to promote or deliver services. Other elements linked with success in scale-up included incorporating efforts to strengthen management capacity, developing quality assurance mechanisms that use participatory approaches, and introducing training programs, particularly when training is linked with supervision, integrated within standing health processes, and designed to be responsive to changes in the health situation. Similarly, an India case study examining programs designed to strengthen HIV control, nutrition and health services found that monitoring systems, focused objectives, good technical design and measures aimed at addressing bureaucratic barriers were all crucial to enabling effective scale-up,<sup>64</sup> while a Chad case study found that a strategy of promoting services in underserved groups was critical in permitting rapid scale-up to occur.<sup>65</sup> Together, the case studies suggest that a failure to address policy and infrastructure constraints can limit possibilities to expand the reach of health services.<sup>65,66</sup>

## “3 × 5” AND ART

The push to provide access to HIV antiretroviral therapy (ART) in low- and middle-income countries, principally in sub-Saharan Africa, is perhaps the most extensive international health scale-up effort in recent history. In December, 2003, WHO with UNAIDS announced an initiative to address the HIV treatment “health emergency”, which aimed to expand ART to 3 million people in developing countries by the end of 2005, equivalent to achieving 50% coverage of individuals requiring treatment in low- and middle-income countries.<sup>67</sup> The 3x5 target was seen as a necessary midway point on the way to achieving universal access to those in need of treatment. It was estimated to require US\$5.5 billion in funding from national and international sources and was considered feasible by WHO.<sup>67</sup>

Although by December, 2005, less than half of 3x5’s desired scale-up had been achieved, large initiatives by the World Bank, the U.S. President’s Emergency Program for AIDS Relief, the Global Fund to Fight AIDS, Tuberculosis and Malaria and other national and international aid organizations succeeded in rapidly expanding ART coverage from about 7% to 20% (from an estimated 0.4 to 1.3 million individuals) in the 2-year timeframe.<sup>67</sup> In 2005 alone, ART coverage nearly doubled globally. The rapid expansion in HIV treatment resulted in part from supply-side changes: large price reductions through increased supply of generics; fixed-dose combination tablets; and discounts from research and development-based companies. Private sector companies, such as Uganda’s Nile Breweries and the Bank of Uganda contributed by offering free ART to their employees. Infrastructure improvements, including laboratory strengthening, were also considerable. The initiatives also

provided substantial investments in training in medical and management areas, including procurement and procurement systems, distribution of medications and supplies, and demand forecasting—all seen as crucial given the relatively high cost of ARV medications and the importance of high levels of patient adherence to avoid treatment failure and the development of resistance. In many African countries, training programs utilized community volunteers and were led in part by universities and NGOs, which facilitated expansion of home-based treatment and alleviated pressure on health facilities.<sup>68,69</sup>

Why then did the 3x5 scale-up initiative, despite such large and varied international investments, fail to meet its objectives? An independent evaluation of WHO's contribution to the initiative produces conclusions that, in retrospect, were to a large extent foreshadowed by the earlier findings of WHO's own Commission on Macroeconomics and Health and related cases studies regarding barriers to scale-up, released close to 3x5's commencement.<sup>67</sup> WHO's evaluation and others<sup>68,69</sup> concluded that more than any other factor, weaknesses in the health systems of targeted countries, in particular human resources for health ("health services level" constraints in the Commission's framework), were responsible for the slower than expected progress. In fact, such constraints had also been signaled midway through the initiative as a likely obstacle to reaching the 3 million coverage goal.<sup>70,71</sup> Underlying the human resources constraints was the systemic and chronic problem of low pay for health workers with access to higher-paying foreign labor markets ("brain drain") and difficulty in deploying medical personnel to facilitate scale-up in rural areas.<sup>68,69</sup> While the Commission cited community involvement as the factor viewed as most critical to health improvement efforts,<sup>72</sup> the 3x5 evaluation suggested that a lack of participation by civil society, especially people with HIV, had slowed ART scale-up in some countries. Similarly, the evaluation cited a failure by WHO to focus objectives and establish an effective program structure in its support role to countries to achieve the 3x5 goal,<sup>67</sup> thus echoing problems detected by the 2003 India case study.<sup>64</sup>

Notably, health services level constraints continue to be viewed as the foremost obstacle to achieving universal access beyond 3x5, with commentators pointing to recurring costs of laboratory equipment and infrastructure maintenance, the need to train and expand the health workforce to avoid negatively affecting healthcare provision outside of HIV; WHO has also recognized the need to distribute and decentralize the ART provision tasks to communities and community health workers.<sup>68,69</sup>

## RAPID TESTS AND SCALING UP SYPHILIS SCREENING

As a second example, the recent availability of a rapid, on-site treponemal test for syphilis with high levels of specificity and, to a lesser degree sensitivity, has been viewed as an opportunity for worldwide scale-up of routine antenatal syphilis screening and treatment.<sup>73–75</sup> Even in countries with low population prevalence, the cost-effectiveness of antenatal screening in preventing congenital syphilis has been established and it may also be cost-saving.<sup>76</sup> Yet, although such evidence and the diagnostic and treatment tools to

prevent mother-to-child transmission of syphilis have been available for decades, universal access to antenatal screening, prophylaxis and treatment has proved an elusive goal, with continuing annual incidence of congenital syphilis estimated at between 713,600 and 1,575,000 cases worldwide.<sup>2</sup>

Availability of on-site rapid tests might also facilitate regular screening and treatment of risk populations by permitting testing beyond the clinical setting.<sup>73</sup> In China, as in a number of countries, national guidelines recommend screening for individuals engaged in sexual risk behaviors, but who do not typically access public health services. Tucker and colleagues<sup>77</sup> discuss the prospects for scale-up of syphilis screening in this context. They emphasize the importance of the availability of evidence of an accelerating epidemic and a responsive government policy environment. However, community, household and health services level constraints remain: assuring appropriate incentives for providers to conduct testing in China's market-based health system and determining who will pay; human resources capacity to conduct screening; stimulating patient demand for testing; determining patient preferences (e.g., finger-prick vs. venous blood testing); organizational structures to permit increased diagnosis, referral and treatment; and establishing cost-effectiveness. While the main advantage of on-site rapid tests is enabling testing in settings that lack laboratory capacity, cost-effectiveness has also been examined, with mixed results to date. For antenatal syphilis screening compared to traditional tests (RPR, VDRL) rapid on-site tests are estimated to be cost-effective in sub-Saharan Africa<sup>78</sup> and Haiti,<sup>79</sup> but not in Tanzania.<sup>74</sup> Compared to VDRL, screening using on-site rapid tests among patients at STI clinics in sex work locations in Manaus, Brazil was not cost-effective.<sup>80</sup> In these contexts, scale-up will therefore depend on willingness to pay the incremental cost of the logistical convenience of rapid versus traditional testing methods.

## SCALE-UP COSTS

As STI programs consider the prospect of expanding, they must project costs at different scales, or service levels to support programming. Yet, evidence remains limited as to how costs change as STI program coverage increases. As one would expect from economic theory, variations in scale across programs tend to explain a considerable portion of variation in cost; for example, in HIV interventions, this share has been estimated at 26–70%.<sup>81</sup> Programs such as voluntary counseling and HIV testing (VCT) with relatively low fixed costs, tend to achieve economies of scale as volume increases and thus a reduced average cost, while the few available studies for other kinds of programs—such as targeted prevention and STI management—have been mixed, some exhibiting economies of scale and others facing reduced costs up to an optimal size, then increasing as resource inputs (e.g., physical infrastructure, personnel) become scarce.<sup>81</sup> Based on fixed costs alone, it is predicted that treatment and prevention of mother-to-child transmission programs (high infrastructure costs) face diseconomies of scale, while expansion of VCT and information, education and communication interventions (low fixed costs)

**Fig. 18.1:** Predicted effect of scale on cost for HIV interventions. IEC: Information, education, and communication; PMTCT: prevention of mother-to-child transmission; STI: treatment of sexually transmitted infections; VCT: voluntary counseling and testing. Reproduced from Kumaranayake L. The economics of scaling up: cost estimation for HIV/AIDS interventions. *AIDS* 2008;22:S23.

would achieve reductions in average cost (Fig. 18.1).<sup>81</sup> An analysis of the first 2 years of the large Indian AIDS Initiative, Avahan, with total costs of US\$16.8 million and reaching more than 134,000 sex workers and clients in 62 districts of four southern Indian states, documented a significant reduction in average cost as well as a 61% share of cost variation explained by differences in scale across the 107 NGOs involved in implementation.<sup>82</sup> However, the analysis did not report how cost responded to scale by each of the different components (education, information, and communication, condom distribution, syringe exchange, STI treatment, and structural interventions). Overall, empirical evidence is limited in this area and STI programs can contribute much-needed information by routinely tracking data on costs and reporting economic analyses.<sup>81</sup>

### BROADER EFFECTS OF SCALE-UP

The immense investment to expand HIV programming in recent years has given rise to a continuing debate regarding the overall impact of these efforts on controlling the HIV pandemic and on health systems. It has been suggested that the relatively greater focus on expanding treatment relative to prevention, coupled with the rapid influx of considerable financial resources for treatment in resource-limited countries, has drawn many community-based organizations away from community mobilization and HIV prevention,<sup>68</sup> even as new infections have continued to outpace the number of individuals commencing treatment by a ratio of 2.5:1.<sup>83–85</sup> At the level of health systems, there is concern that the international focus on HIV has diminished resources available for other health priorities.<sup>86–89</sup> Others contend that HIV investments benefit the health system overall.<sup>90</sup> With little evidence available regarding these issues, the *Bellagio HIV/Health Systems Working Group* has recently proposed a research agenda to improve understanding of the impact of HIV scale-up on various aspects of health systems, with an emphasis on orienting “vertical” versus “horizontal” approaches to incorporating HIV within the health sector.<sup>91</sup>

## Conclusions

This chapter has outlined essential aspects of STI program implementation. The main conclusions from this chapter include:

- Countries need a reproductive and sexual health national strategy that serves as a framework for policies, laws, and programs related to STIs including HIV. It is important that the policy framework and the organization of programs provide ways to best link sexual and reproductive health, and STI and HIV services in different settings. Removal of unnecessary restrictions from policies and regulations, in order to create a supportive framework for reproductive and sexual health, is likely to contribute significantly to improved access to services.
- Managers of STI control programs are responsible for ensuring that program resources—human, material or financial—are used in the most cost-effective way to reach the program’s stated objectives. To fulfill this responsibility, managers must assess the available resources, the infrastructure and the extent of the STI problem. They must prioritize the strategies and activities that are most likely to achieve the program’s objectives cost-effectively. Carrying out these strategies and activities requires a detailed work plan with a realistic timeline and budget. A work plan’s implementation must be monitored against set targets, and an evaluation will reveal how successful the program has been in reaching its stated objectives.
- The three main objectives of an STI control program are: interruption of the transmission of STIs; prevention of the development of diseases, complications and sequelae; and reducing the incidence of HIV infection. These can be achieved by a combination of the following core interventions strategies: (i) Behavior change strategies to promote safer sexual behavior, consistent and correct condom use, and appropriate healthcare-seeking behavior; (ii) Delivery of services for management of STI patients and their partners; and (iii) Condom programming.
- STI programs face constraints beyond funding when attempting to scale-up. Important lessons have been distilled from systematic reviews of health development work and specifically with respect to HIV interventions such as WHO’s 3x5 effort. Chief among these are the importance of community participation strategies, sufficiently addressing limitations on health capacity, focusing objectives and implementing well-planned and coordinated participative monitoring and supervision mechanisms. Thoughtful review of why past scale-up efforts have met with success or failure and learning from this experience should be part and parcel of any new scale-up initiative. As average costs may increase or decline as operations expand, all scale-up attempts should include detailed cost forecasting to anticipate changes. The impact of large investments in specific STI strategies—such as HIV treatment—on service provision in other health areas remains poorly understood; all STI programs should seek to achieve synergies to strengthen the overall health system.

# Integrating STI Prevention, Care, and Treatment with Other Sexual and Reproductive Health Services

Kathryn Church

# 19

## Introduction

There are a variety of possible ways that health programs can scale-up access to STI prevention, care, and treatment. In various settings, STI programs target high-risk populations with little attention paid to bringing services to the wider community. In these contexts, care may be delivered through specialist STI units or centers, or through specialist outreach programs aiming to deliver care to specific groups, such as sex workers. In settings of rising community STI prevalence, integration of STI prevention, screening and treatment into primary care or with other types of health services offers an important strategy to broaden service scope and scale-up access and coverage. Integration of services can also be a more cost-effective and efficient way of delivering healthcare than vertical programs.

Integrating healthcare entails actions at both service-delivery and policy levels. At the service-delivery level, a range of service modalities are possible to integrate STI care, including one-stop shops offering comprehensive sexual and reproductive health (SRH) care, comprehensive primary healthcare (PHC) which includes STI services, semi-specialist STI providers or units within larger health services, or effective referral models to specialist care. The specific service modality chosen will depend on a range of factors, including the level of care that is being provided (i.e., whether outreach, primary, secondary, or tertiary), the population being served (including the specific local STI epidemiology), the pre-existing structures and infrastructure of the health system and the human resource capacity to deliver STI care.

The capacity to deliver integrated services also depends on the degree of intersectoral collaboration among health programs. Within national or state-level health programs, STI services have historically fallen under the remit of a range of different departments, including SRH, HIV, and/or communicable diseases. Integrating policy and programmatic components may therefore be a prerequisite to integrating services.

This chapter will discuss how integrated services are currently being considered within the sphere of public health, with a focus on health systems in low- and middle-income countries

(LMICs). It will start with a discussion on the meaning of integrated services, and how understanding models of integration are crucial for quality STI programming. It will then give an overview of the history of shifts between vertical and integrated health programs, and the reasons for these trends. It will further discuss the current drive and rationale for more integrated models of care, focusing particularly on STIs and other SRH services. It will then outline the specific models of integrated services being considered, including integration into SRH services, as well as bringing SRH care into more vertical STI and HIV services. Lastly, it will discuss specific challenges to integration and strategies to overcome them.

## Vertical and Integrated Approaches in Healthcare

### A SHORT HISTORY

Current public health debate on integrated services has been strongly influenced by a recent history of oscillations between what have been described as “vertical” health programs, and more “horizontal” or integrated approaches. Vertical or “disease-specific” programs result from political decisions that recognize the importance of specific health problems based on epidemiological, economic, social, cultural, or political criteria.<sup>1</sup> They derive from vertical analyses, which see one health problem as independent of others, and are associated with a more medicalized model of infectious disease control.<sup>2</sup> Vertical approaches have been successful in controlling particular diseases, such as smallpox or polio; in managing groups of linked health problems, such as diarrheal diseases; in managing the health problems of key subpopulations, such as mothers and children; or in structuring activities, such as immunization.<sup>1</sup> Attractive to international donors and partners, they are usually well-funded through extra-budgetary resources, tightly managed, with specific objectives and highly qualified personnel.<sup>2,3</sup> It has also been noted that vertical programs are most appropriate when the technology of disease control is very sophisticated, and very different from common tasks requiring specific skills.<sup>3</sup>

Although always present, vertical health programs have grown in prominence over the past few decades as international funding for the priority health programs of LMICs has increased. However, problems were identified with disease-specific approaches as early as the 1960s, when a WHO study group on “the Integration of Mass Campaigns against Specific Diseases into General Health Services” reviewed both vertical and integrated approaches to public healthcare, and concluded that integrated approaches were more sustainable, efficient, and convenient for users.<sup>4</sup> The vision of comprehensive PHC articulated within the Declaration of Alma Ata in 1978 was, in some respects, a response to verticalized health programing. However, this vision was seen by many as too ambitious, in particular given public sector spending constraints imposed in many developing countries from the 1980s onwards.<sup>5</sup> Instead, selected strategies or interventions were promoted and ‘selective PHC’ ensued,<sup>6</sup> leading to programs such as the Expanded Program on Immunization, and the development of packages of “essential services”.<sup>7</sup>

## INTEGRATION IN SRH

Within the field of SRH, similar tensions have evolved. A narrow focus on family planning programs and population control in many countries, to the neglect of broader SRH goals and women’s rights, led to the call for a comprehensive and integrated response to SRH care. At the International Conference on Population and Development (ICPD) in 1994, 179 countries signed up to a Programme of Action on delivering this comprehensive package of services, which included family planning; abortion (where legal) and management of abortion-related complications; antenatal care (ANC), delivery, postpartum, and newborn care; and the prevention and management of infertility and RTIs and STIs including HIV.<sup>8</sup> This pledge has been re-emphasized through various other international policy documents since then, including ICPD reviews in 1999, 2004, and 2009; and through WHO’s *Reproductive health strategy to accelerate progress towards the attainment of international development goals and targets*,<sup>9</sup> as well as through the renewed commitment to achieving universal access to reproductive health by 2015 as part of the Millennium Development Goals global strategies<sup>10</sup> (see Box 19.1 for a full list of policy statements on SRH integration).

Yet again, however, the reality of trying to deliver a comprehensive package of care in resource-constrained settings with weak PHC infrastructure inhibited fulfilment of these integration goals. In the late 1990s, evidence emerged of the difficulties confronting reproductive health services in expanding beyond their service focus and their traditional patient base of married women.<sup>11–13</sup> Many programs were failing to reach out to target groups with the greatest sexual health needs, namely men and adolescents. Programs also lacked the capacity to develop feasible, acceptable, effective, and cost-effective strategies, especially for delivering STI management.<sup>14,15</sup> Integration within SRH programs therefore became a compromise between the rhetoric of comprehensive care and the reality of service delivery.<sup>11</sup>

## HIV PROGRAMS

At the same time as challenges to SRH integration were being identified, the HIV pandemic was emerging and substantially increasing international funding to HIV and other communicable diseases through mechanisms such as the Global Fund to Fight AIDS, Tuberculosis and Malaria (GFATM), and through initiatives such as the US President’s Emergency Fund for AIDS Relief (PEPFAR).

While family planning and MCH programs evolved either within, or closely connected to PHC programs, HIV programs, on the other hand, mostly evolved as specialist vertical programs from the outset. This specialization was fuelled by donors and technical specialists who were more focused on the epidemiological and clinical aspects of infectious disease control.<sup>16</sup> As the epidemic grew exponentially in the early 1990s, the rationale to focus on HIV separately from other health programs became even stronger. The creation of a separate United Nations agency on HIV in 1996 (UNAIDS) demonstrated clearly the impetus to tackle the virus within a specialized framework, independent of other SRH problems and other infectious diseases.<sup>17</sup>

Over the past 5 or 10 years, however, weaknesses of the health systems within which HIV programs were being implemented have prompted recognition of the need to address the disease through a more integrated approach. As a consequence of the strong financial support that HIV programs received, they have often been found to be stronger than the prevailing PHC structure within which they are operating. Studies even began to report on the integration of primary care services *into* vertical HIV services.<sup>18,19</sup> Not only has there been a shift to a “public health approach” to HIV management,<sup>20</sup> but also a multitude of calls to use HIV funding for health systems strengthening.<sup>21,22</sup> Evidence has also emerged that strengthening healthcare through the use of HIV funds can also benefit other health services, including reproductive health services.<sup>23</sup> Lastly, since HIV is a chronic condition that requires a wide range of interventions and activities along a continuum of prevention, diagnosis, treatment,

and palliative care, its placement under verticalized programs may not be cost-effective in the long term: in essence, any vertical HIV structure has no choice but to duplicate virtually a standard multi-function health service.<sup>1</sup> The long-term need for chronic care therefore provides a strong rationale argument for the management of HIV within an integrated structure.

## A FALSE DICHOTOMY

Given the potential of using vertically funded programs to strengthen health systems, the dichotomy between vertical and horizontal approaches may be a false one. Further, many interventions may be organized by vertical management structures but delivered through primary or integrated programs.<sup>3</sup> Within more developed health systems, it is clear that strong PHC can be supported by vertical structures and specialist medical programs. General practitioners (GPs) in the United Kingdom, for example, interact within multi-disciplinary teams and are supported by a highly specialized medical system at the secondary and tertiary levels. Various reviewers have concluded that optimal care must be based on a synergy of vertical and horizontal approaches, with specific models based on local epidemiology, organizational, functional and resource capacities, and the socio-cultural values of the country.<sup>1,3,5,16</sup> This has become manifest in the approach of hybrid 'diagonal' health financing which aims to utilize vertical funds to strengthen health systems.<sup>24</sup>

## Understanding Integration

While a considerable literature on integration of STI and other SRH services has been published in recent years, the concept often remains poorly defined. Integration in the health sector should be understood as both a process (the action of integrating) as well as an outcome in itself (integrated services). The former implies bringing together two or more components of care that were previously separate, or adding new components of care to an existing service, resulting in a range of organizational changes to service provision.<sup>25</sup> Integrating care in this way is used as a tool to overcome fragmented healthcare within systems where vertical disease-specific programs predominate. The concept of *integrated* care, on the other hand, is often equated with comprehensive PHC, and implies the delivery of a core package of services.<sup>1</sup> A 1990s WHO study group on integrated care defined integrated services as holistic, comprehensive PHC, organized through a decentralized and efficient district health system.<sup>5</sup>

Various typologies of integration have been proposed over recent years and they describe the concept at different levels of program management and delivery. It has been categorized as either 'functional', implying the integration of different healthcare functions,<sup>5,26,27</sup> or 'organizational' or 'administrative', implying the integration of management structures and processes, but not necessarily bringing together service tasks.<sup>26</sup> To some, while administrative integration may be helpful, functional integration is the important endpoint to provide holistic, integrated care to patients.<sup>26</sup> Integration has also been described as the 'bundling

of services', implying an integrated approach to client or patient management<sup>28</sup>; a useful example being the Integrated Management of Childhood Illnesses (IMCI). It can also be categorized as 'temporal', implying integration at one point in time so that a patient can access any type of care at each contact with the health service, or 'spatial', with all services provided by the same team or in the same room, but perhaps at different points in time.<sup>1</sup> This last also implies that integration is a 'continuum', implying continuity of care over the life-course.<sup>29</sup> Within the context of SRH, STI, and HIV, integration can also occur at the preventive level (information, education, and behavior change), the treatment level (clinical diagnosis and management), and at a policy level.<sup>30</sup>

When considering service delivery, it can be useful to classify different types of integration, including 'provider-level integration', meaning a range of component services are offered by one provider; or 'room-level integration', meaning a range of services are offered in one room (which may or may not be given by one provider); or as 'facility-level integration', with patients accessing different components of care within one site, but with different providers and in different rooms. While some may dispute this last as being integrated care, others consider it as such as long as the provider actively encourages patients to use other services during that visit.<sup>12</sup> Integration can also be considered as 'active', implying that providers must assess a range of possible health needs over and above a presenting problem or condition; or 'responsive', implying that patients are the ones who take the initiative to discuss their problems and demand a service response.<sup>31</sup>

At a more programmatic level, the terms 'linkages' or 'synergies' between more verticalized health programs have gained currency in recent years.<sup>32</sup> This is primarily borne out of the recognition that not all services can or should be delivered at one point in time by one provider, as well as the realization that subspecialist or specialist care will always be required at some level. What is important, therefore, is to build strong linkages between different programs and ensure that effective referral and continuity mechanisms are in place between different levels and different types of healthcare.<sup>33</sup>

Ultimately, therefore, integrated care implies either having multi-purpose staff, a multi-purpose team and clinic, or an effective referral mechanism to address a range of different healthcare needs.

## Rationale for Integrated Approaches in SRH

Unintended pregnancy and STIs, including HIV, often share the same root cause, namely unprotected sexual intercourse. Considering HIV specifically, the majority of infections in most settings are sexually transmitted or are associated with pregnancy, childbirth, and breast-feeding. In addition, the various SRH morbidities share root causes, including poverty, limited access to appropriate information, gender inequality, cultural norms, and social marginalization of the most vulnerable populations.

Many have therefore considered it logical for reproductive health services to be at the forefront of efforts to prevent STIs and the sexual transmission of HIV.<sup>14</sup> The presumed benefits of integrated approaches will be discussed.

## PATIENT SATISFACTION

Provision of a relatively broad range of services within one clinic or by means of a single visit to one provider has been assumed to increase patient satisfaction with care. In verticalized or disintegrated services, patients may have to visit several facilities to address diverse SRH needs, or may have to queue multiple times within one facility. In fee-paying institutions, patients may also achieve savings in settings where they can get all their services in one visit. However, while having all your health needs addressed within one visit may have clear advantages for the consumer, the integration of STIs and HIV into reproductive health consultations may also have its drawbacks for some patients. It may require that a risk assessment of sexual behavior be conducted, and in some instances a pelvic examination as well, both of which may be off-putting. Older, married women may take offence at the suggestion that they may be at risk for STIs. Further, patients who are in a rush, for example repeat ART users coming for monthly refills, or repeat family planning patients coming for injections, may object to STI screening, or other SRH counseling if initiated by the provider.

## SERVICE ACCESS AND COVERAGE

Integration has been proposed as an important means to increasing health equity by increasing access to and utilization of services. In many settings where transport is costly and unreliable, where queues are long and patient loads are high, providing a range of services through one provider or under one roof (i.e., a 'one-stop-shop') should theoretically increase access to and use of services. In many settings, referral systems between different health institutions are weak, and patients referred either internally or externally may not reach their destination. One study from West Bengal, for example, found that adding HIV testing and counseling within a functioning SRH service (as opposed to referring patients to a separate service adjacent to it) led to uptake of both SRH and HIV service arms, as well as reducing costs.<sup>34</sup> An integrated service may also expand the patient-base of services. Specifically, integrated approaches can help reproductive health programs move beyond their focus on women, and involve men, adolescents, sex workers, and other high-risk groups within a more comprehensive healthcare program.

However, referral models may also be effective in certain circumstances. One African study that compared a referral model of HIV testing within a family planning service with an on-site model found mixed results: although providers at the on-site model were more effective at offering HIV testing to family planning patients, those attending the referral model were more likely to accept a test.<sup>35</sup> The authors suggested that this difference reflected a preference for anonymous testing at

a separate site. Further, even in purportedly integrated settings where providers have been trained to deliver a broader package of care, missed opportunities for integrating care persist. In particular, what is unclear is how providers of integrated services manage to move beyond the condition presented by the patient to explore other health topics, i.e., the process of "active integration" discussed earlier. One report shows that breadth of service can be increased through the use of screening algorithms, although it also indicates that a high patient-load can be prohibitive to increasing the number of services accessed per visit, even when providers are supported by training and job aids.<sup>47</sup> The provider role is particularly important for STI services, given that patients in many contexts rarely take the opportunity to report STI/RTI symptoms spontaneously in consultations.<sup>36</sup> Furthermore, studies conducted in integrated health centers have shown that patients are also often unaware of the range of services available to them.<sup>37</sup>

## STIGMA, PRIVACY, AND CONFIDENTIALITY

During the 1990s, there were concerns that addressing STIs within reproductive health contexts would be stigmatizing for those patients attending for STI services, and that providers of family healthcare would have difficulty in adjusting to meet the needs of a high-risk group.<sup>16</sup> On the other hand, offering STI and HIV services through services not identifiable with first-line STI or HIV care may reduce the risk of social stigma for patients and reduce barriers to services such as HIV testing or STI management.<sup>32,38</sup> A review of program effectiveness of the integration of STI and HIV with family planning services found no evidence that integrated services increased stigma toward services or patients, and may indeed be a more comfortable environment for patients.<sup>39</sup> However, the value of integrated care in reducing service-related stigma is dependent on the degree to which reproductive health services are able to maintain confidentiality. This may be jeopardized where STI or HIV patients are seen in consultation rooms clearly marked for their care. Moreover, some evidence suggests that people living with HIV may prefer specialized HIV care to integrated care because of the poor treatment they receive in integrated services, including lack of confidentiality and privacy, discrimination and negative attitudes from providers, and otherwise substandard care.<sup>40,41</sup>

## QUALITY OF CARE

Integrating a new service component into an existing service has the potential to improve quality of care by increasing the breadth of care and by providing more patient-centered care, or to diminish quality as breadth is achieved at the expense of depth.<sup>42</sup> In particular, quality may suffer as providers struggle to broaden their scope of care to more sensitive areas of sexual health counseling and care. Although in theory reproductive healthcare providers already possess many of the technical and service skills required to offer STI-related information and services for prevention, studies suggest providers of reproductive healthcare face difficulties in

addressing STI and HIV prevention and conducting behavioral risk assessments for patients.<sup>43–45</sup> Many studies published in the late 1990s also found that reproductive healthcare providers were struggling to effectively deliver quality STI services as programs lacked the capacity to develop feasible, acceptable, effective, and cost-effective strategies for STI management.<sup>14,15</sup> These challenges are discussed further under heading “Challenges and Strategies for Integration”.

### COST-EFFECTIVENESS

Integration of services can improve efficiency through the optimal use of scarce resources and avoiding duplication of effort. It offers cost savings by sharing staff, facilities, equipment, and other administrative and overhead costs.<sup>14,16</sup> Cost-savings seem most likely when many patients are able to access more than one service, as has been demonstrated in a recent Indian study integrating SRH and HIV services.<sup>34</sup> In another Kenyan example, the combined costs of integrated HIV and family planning services amounted to less than half the estimated costs of a stand-alone VCT site.<sup>35</sup> However, it seems clear that staff must have excess time available before service integration begins if cost-effectiveness or increased productivity is to be achieved.<sup>46,47</sup>

### IMPACT ON HEALTH

Investigating a direct link between a service delivery configuration and health outcomes is problematic, given the diverse range of other determinants on health outcomes. In theory, making improvements in the areas already discussed, such as access, coverage, and stigma, should ultimately lead to improved outcomes. Lower level outcomes may be more realistic to measure and achieve, for example improved condom utilization where STI and HIV prevention interventions have been added to a family planning service; higher rates of HIV testing and access to HIV care and treatment following integration; or higher rates of STI screening and treatment in integrated settings. For example, two recent pre- and post-test studies on integration of HIV testing into FP services in South Africa and Kenya reported significant increases in discussions of condom use and dual-protection counseling.<sup>35,48</sup> Another report from Ethiopia found that being attended by the same provider in the same room was positively associated with patient-initiated HIV testing and negatively associated with patients' HIV infection, compared with being seen elsewhere in the facility.<sup>49</sup> Important, *albeit* limited, evidence is also emerging that promotion of FP for HIV-infected women (usually as part of FP/MCH services) can reduce pediatric HIV by preventing unintended pregnancies, a strategy likely to be significantly more cost-effective than the provision of PMTCT.<sup>50</sup>

### Models of STI Integration

STI services are most commonly delivered within the context of PHC, SRH care, or more specialized STI and HIV services. A range of different health services make up the different

components of SRH and HIV care, and within these feature a range of possible interventions that can be delivered to broaden the service scope of a pre-existing (or ‘baseline’) service. Table 19.1 gives an overview of the different service configurations that are possible for integration. These services and interventions will be discussed in this section, with a focus on scaling-up access to STI prevention, care, and treatment.

Before discussing the details of service configurations, however, it is worth noting that the exact model of integration within a health system is dependent on the context in which it is being undertaken. Integration is shaped by the mission of the organization involved, the local context, the needs of the patients and the community, the potential local partnerships for referral, and the organization's own capacity.<sup>51</sup> It is also influenced by the epidemiological context, in particular the STI and HIV prevalence and distribution. It is therefore critical to assess the current health systems and service structures and review current service configurations and identify gaps in service delivery.

### SERVICES AND INTERVENTIONS INTEGRATING STI AND HIV INTO SRH SERVICES

Integration of STIs and HIV into other reproductive health services include four main groups of activities: firstly, primary STI and HIV prevention (including health education and counseling, and provision of educational materials and condoms); secondly, the diagnosis and management of STIs, (screening, diagnosis, clinical management, treatment or referral for treatment, partner notification, and secondary preventive counseling); thirdly, integration of HIV services into SRH, including PMTCT, HIV testing, and treatment; and lastly, integration of other SRH services.

### STI and HIV Prevention

On the prevention side, reproductive health services can be used to promote safe sex. In its guidelines on both family planning and STI integration, WHO recommends that counseling on STIs become an integral component of contraceptive decision-making and maternal health counseling.<sup>52,53</sup> Family planning patients should be counseled on the effectiveness of contraceptive methods for infection prevention, as well as contraceptive efficacy. Different protection strategies can be suggested to patients, including dual protection (condoms alone or with another method), safer sexual practices, delayed sexual debut, and partner reduction (where relevant).

However, the promotion of condoms in reproductive health programs presents a challenge. Over the past 30 years, providers have generally favored more technically advanced, effective, and longer-term methods, disregarding the condom as an effective method for preventing unintended pregnancy. Condoms, where promoted, have almost exclusively been targeted at young people, with an emphasis on use for nonmarital sexual contacts. Efforts are needed to change the beliefs and practices of providers, to promote the emphasis on both prevention of pregnancy and

PITC, provider initiated testing and counseling; PMTCT, prevention of mother-to-child transmission; VCT, voluntary counselling and testing.

protection against infection. Research has also shown that the promotion of condom use within marriage is achievable.<sup>54</sup>

Delivering more holistic sexuality counseling can also be an important preventive intervention. Discussing sexual behavior helps patients understand better their own risk of both unintended pregnancy and STI and HIV infection.<sup>28</sup> Studies have shown that many patients have concerns about their sexual health and appreciate the opportunity to ask questions and share their problems in a safe environment.<sup>55</sup> However, health workers need to be properly trained to introduce discussions around sexuality into reproductive health services.

## STI Screening, Diagnosis, and Management

Integrating the detection and management of STIs and RTIs into some reproductive health settings can be more complex, and is limited to a large degree by current technologies and resources available. Screening for STIs may be undertaken in well-resourced centers, including speculum and bimanual examination to look for signs of cervical infection or PID, screening for early diagnosis of cervical cancer, or screening tests for syphilis, chlamydia, or gonorrhea. Most tests available are complex and costly, require intensive training for providers and are simply not feasible in

resource constrained settings.<sup>56</sup> Furthermore, the current costs of providing laboratory screening for many STIs is beyond the resource capacity of most public health systems in many LMICs. In one African country, for example, the estimated additional cost of laboratory screening per family planning visit would be over US\$25.<sup>14</sup>

The recent development of point-of-care diagnostic tests (rapid tests) is a major technological development that can support integration of STI services into reproductive healthcare.<sup>57</sup> Until recently, syphilis screening was limited to pregnant women, but access can now be scaled-up through the use of rapid tests which can be performed outside a laboratory setting with minimal training and no equipment. Research is also currently being conducted on the development of rapid tests for chlamydia and gonorrhea.<sup>58</sup> Nevertheless, given the scarcity of STI diagnostic tests, syndromic management remains the core intervention in the WHO strategy for STI control in resource-poor settings, delivering immediate prevention and care for people presenting with clinical syndromes usually associated with the presence of an STI or RTI.<sup>57,59</sup> The value of the syndromic approach is that it is relatively simple to use, and can be incorporated into all levels of the healthcare system, in both the public and private sectors. It was through this approach that most reproductive health services began to integrate STI treatment into their services in the 1990s. However, its poor performance in managing abnormal vaginal discharge in women means that is not a magic bullet for STI control within primary care settings, and WHO now recommends that the management of vaginal discharge should be based on the assumption that the infection is a vaginal infection.<sup>53</sup>

A range of STI screening interventions are also recommended during and after pregnancy and in childbirth. These include STI and RTI assessments in ANC; provision of syphilis screening, treatment, and partner treatment; testing for bacterial vaginosis and trichomoniasis if there is a history of spontaneous abortion or preterm delivery; an offer of VCT and access to PMTCT for positive women.<sup>53</sup> During labor and delivery, actions should also be taken to identify infections that may not have been detected during ANC, and to intervene where possible to prevent and manage STIs and RTIs in the newborn.

## HIV Services

Different strategies to scale-up HIV within PHC and SRH testing include VCT (allowing patients to independently make a choice to attend a health facility to get an HIV test), and more recently, provider-initiated testing and counseling (PITC) (encouraging the promotion of HIV testing within a range of different health settings through an “opt-out” approach).<sup>60</sup> In all HIV epidemics (whether low-level, concentrated or generalized), WHO now recommends that HIV testing should be proposed by healthcare providers as part of standard care to all clients or patients who present with signs or symptoms that could indicate HIV infection; to infants born to HIV-positive women; to malnourished children who do not respond to nutritional therapy;

and to men seeking male circumcision. Within generalized epidemics (where prevalence is consistently over 1% in pregnant women), WHO recommends that HIV testing be recommended to all adults and adolescents seen in health facilities, including all those attending any kind of SRH service.

PMTCT services are another critical HIV service that may need to be integrated into reproductive healthcare. Such programs usually consist of upgrading basic MCH services to include the introduction of HIV testing, ARV prophylaxis for HIV-infected pregnant women, safe delivery practices, counseling and support for safe infant feeding practices, follow-up of HIV-positive women, and prevention counseling with condom promotion.<sup>61</sup> In addition to these core services, however, other elements of SRH care for positive women may need to be considered (see next section). Follow-up of HIV-positive mothers is also a critical issue for an integrated service. In many programs in LMICs, women do not continue to receive ART outside the PMTCT program. Care is usually limited to referral to community-based care and support services. However, fear of stigmatization may make women reluctant to disclose their HIV status either in or outside the ANC clinic.

## Other Interventions

Other services and interventions that can be provided within an integrated SRH service include infertility counseling and treatment, cervical cancer screening and treatment, and violence services.

Most of the infertility in LMICs is attributable to damage caused by RTIs or STIs, notably gonorrhea and chlamydial infection, making it an important SRH concern that services must address. Aside from primary prevention and treatment of infections, other possible strategies include addressing unsafe abortion and substandard obstetric care, providing infertility treatments through assisted reproductive technologies and providing comprehensive counseling for infertile couples. One successful program was implemented by the Family Planning Association of India (see Box 19.2).

Cervical cancer prevention, screening, and treatment are also important services that may be integrated into pre-existing primary care settings. Primary prevention through the HPV vaccine is an ideal way to prevent infection, since most people are exposed once they become sexually active. However, since the target cohort for the vaccine is girls aged 10 to 13 years, SRH services may not play a large role in national roll-outs. On the other hand, reproductive health services, in particular family planning programs, offer an important opportunity for screening. Screening and treatment programs have been shown to be effective in reducing mortality in women since the cure rate for invasive cervical cancer is closely related to the stage of disease at diagnosis and the availability of treatment. However, achieving a high level of coverage is essential for cancer control programs, and organized national prevention programs are most cost-effective.<sup>62</sup> Since Pap smears are generally used for screening only in middle- or high-income settings, one low-cost option that can be integrated into SRH is visual inspection with acetic acid (VIA).<sup>63</sup> The

**Box 19.2** Program Examples Integrating STI/HIV and Other Healthcare into SRH Services***Integrating STI into reproductive health services in sub-Saharan Africa and Indonesia***

In pilot projects conducted in Kenya and Zimbabwe, family planning and ANC services were systematically reoriented to include STI control and treatment. Following a needs assessment, staff were trained, drug supplies guaranteed, and a standardized checklist developed to guide staff through all components of an integrated consultation. This consultation comprised a full history, a clinical examination (including pelvic examination), a risk-assessment, and education on STIs and HIV. Research found the various reorientation activities were important, and that use of the counseling checklist, in particular, was useful to guide providers through an integrated consultation.<sup>13,101</sup>

Experience from Indonesia has shown that integration of STI prevention and care into family planning clinics is feasible even in low prevalence settings, and does not necessarily require large infrastructural investments. A pilot program in North Jakarta demonstrated that the equipment and supplies available at the community health center were adequate for the provision of integrated services. It was found that being able to offer privacy and confidentiality in a well-run clinic, coupled with well-trained providers with nonjudgemental attitudes, were key to success. An important lesson was that the process of reorienting and training providers to integrate STI prevention and care into family planning settings took more time than expected.<sup>102</sup>

***Adding HIV services to SRH in India***

The Family Planning Association of India integrated HIV services into SRH care in Lucknow. The needs and feasibility assessment was conducted first. Staff were initially sceptical about adding VCT to their workload, since they felt that it might change the profile of service users, that the patient perception of the clinic might change, and that the HIV services might take over the clinic. There were also concerns about increased staff workload, as well as occupational exposure to HIV. In this situation, integration of services was achieved gradually: nurses began to explore their patients' risk of STIs and HIV, so they could refer them to VCT services. Educational materials were developed on HIV prevention and care, and activities were carried out to raise awareness of HIV in the clinic. Procedures for universal precautions and sterilization of equipment were also reviewed and revised to reduce fears about occupational exposure. After several months, all staff saw that they had an important role in HIV services, and in maintaining a low rate of HIV prevalence in the region, and full integration of services could commence.<sup>51</sup>

***Infertility care within SRH***

The Family Planning Association of India incorporated infertility care into its *Comprehensive Reproductive Health for All* project. One of the first areas to roll out this service was Bhiwandi, where a specialized infertility service was integrated with other reproductive health services.<sup>102</sup> The program included staff training and the development of new standards and protocols for infertility care. A specialized infertility clinic was organized at certain times of the week, where couples (rather than individuals) could be counseled. Infertility services provided included screening and diagnosis of infertility (including semen analysis for men, and physical examinations, cervical mucus studies and blood tests for women), diagnosis and treatment of STIs, counseling and education on fertility and the menstrual cycle and provision of counseling and emotional support for couples with primary infertility. Treatments for infertility included counseling on effective sexual intercourse practice (extending intervals between ejaculations to allow sperm counts to build up), sperm washing, artificial insemination, and referrals for more sophisticated treatments (such as testicular sperm aspiration and sperm auto-preservation). Infertility services proved to be one of the more popular services offered at the clinics, forming one-tenth of the total patient load. However, despite these advances, this clinic was also limited by the local health system capacity. Staff were not able to diagnose the cause of infertility in the majority of cases (65%) due to the high costs of diagnostic techniques and the difficulties of infertility diagnosis. Also, many of the treatments offered were costly, and would be beyond the reach of the poorest patients.

***Addressing violence within SRH in Brazil***

Both government and NGOs are responding to violence against women in Brazil. In government facilities, services were created in a number of hospitals to address the consequences of sexual violence. The programs offered emergency contraception, prophylactic antibiotics for syphilis, gonorrhea and chlamydial infections, immunization against hepatitis B, antiretroviral drugs to prevent HIV transmission, pregnancy termination, and psychological counseling. Women were also advised to report assaults to the police. On the basis of these experiences, the Ministry of Health in 1998 published standards for the prevention and treatment of the consequences of rape in adult and adolescent women. The number of hospitals offering such services increased from 3 in 1997 to 71 by the end of 2001.<sup>104</sup>

The Brazilian Civil Society for Family and Well-being (BEMFAM) started including services for victims of gender-based violence in its SRH services in 2000. The first phase concentrated on improving the knowledge and attitudes of health staff. In several workshops, methods of sensitizing staff to the problem of gender-based violence were tested, and a service protocol was developed. Systematic screening was started in 6 clinics to collect data on the prevalence of gender-based violence, and its different types. The need for a referral network soon became apparent, since health workers were reluctant to screen if they could not offer services. BEMFAM has compiled a directory of existing services for victims of gender-based violence.<sup>105</sup>

development of effective follow-up and referral mechanisms is also an integral component of screening programs.

SRH services may also offer a potential entry point for identifying and addressing violence against women (VAW).<sup>64</sup> Health services should be prepared and health providers trained to respond appropriately to VAW and, where appropriate, to recognize signs of intimate partner violence and other forms of sexual violence. Strategies include screening, treatment, and referrals to more specialized care. There is, as yet, no consensus on whether, when and how women should be systematically screened, in particular for intimate partner violence, since screening may impact on a woman's future risk of violence. Screening processes must ensure privacy and confidentiality, and be conducted in

safe and nonjudgemental ways. Within SRH, the provision of post-rape services is critical, including providing emergency contraception, abortion services, post-exposure prophylaxis (PEP) for HIV and other STIs, counseling and referral to other medical, psychological, social, and legal services. Violence services can also be provided through separate specialized facilities, for example through "One-Stop Crisis Centres", which are often co-located with emergency departments in hospitals.<sup>65</sup>

**INTEGRATION INTO STI AND HIV SERVICES**

Although most emphasis continues to be placed on integration of STI and HIV services into reproductive healthcare and other

primary care settings, some programs have also begun to integrate family planning or other SRH care into newly emerging STI and HIV services. This section will discuss strategies for both integration into specific STI services, and also integration aimed at meeting the SRH needs of people living with HIV (PLHIV).

## Integration into STI Services

More specialized STI services may need to consider addressing the broader SRH or HIV needs of their patients. Such services may be targeting high-risk groups, such as sex workers or men, who also have other healthcare needs beyond STI treatment. Many STI services also continue to have too narrow a focus on treatment, neglecting an important opportunity for prevention counseling and condom promotion with patients who are evidently at high-risk. Box 19.3 contains an example of an Indian STI program that was successful in moving beyond its narrow focus to deliver more holistic care, including family planning and HIV services. STI clinics also play an important role in identifying PLHIV and in managing their STIs.<sup>66</sup>

## Integration into HIV Services

HIV services, including both VCT and treatment programs, need to consider a broader and more integrated approach to meet the diverse needs of their patients.<sup>67</sup> Studies have shown that a high percentage of VCT and PMTCT patients have an unmet need for family planning services.<sup>19</sup> Many programs are now using VCT as an entry point to deliver family planning and other SRH services (see Box 19.3). If patients test HIV-positive, they may have multiple health needs. Not only are PLHIV vulnerable to SRH problems, such as STIs, but they are also often in need of counseling on reproductive choices. Advances in ART provide renewed optimism about the future and increased confidence in having children. Studies have shown that PLHIV in many settings have unmet needs for contraception, as well as for counseling on pregnancy planning, abortion, infertility, and sexuality, among others.<sup>68–70</sup>

Many health professionals perceive the SRH needs of women living with HIV to be almost exclusively related to PMTCT, which has led to insufficient attention being paid to their other reproductive needs.<sup>71</sup> HIV-positive women face a range of dilemmas, discrimination, and barriers in upholding their reproductive rights to pregnancy and motherhood. Sexuality counseling has seldom been part of the counseling for positive women, since programs have tended to focus on the negative aspects of HIV, and have shied away from promoting positive living.<sup>72</sup> Women and men living with HIV report fear of infecting others, fear of disclosure, and violence and discrimination if their HIV status becomes known. They also report guilt, shame, anger, and ill-health resulting in physical and psychological effects on sexual desire and pleasure. In addition, the widespread promotion of abstinence by religious and public health organizations has contributed to the expectation that people with HIV should no longer have sexual lives.<sup>73</sup> Furthermore, HIV-positive women may experience a negative impact on their sexuality from HIV disease itself or from the side-effects of ARV drugs.<sup>74</sup>

### Box 19.3 Program Examples Integrating SRH into STI/HIV Services

#### *Integrated SRH services for sex workers in Mumbai, India*

The Aastha Project, run by FHI, is a community-led initiative in Mumbai that provides preventive and clinical services to sex workers, coupled with the promotion of an enabling environment through social mobilization and empowerment initiatives. Within the service component, STI clinics acted as hubs for the provision of family planning and HIV services to sex workers. The comprehensive package of services offered included screening and testing for STIs, counseling on safer sex and condom use, treatment compliance, partner treatment and risk reduction, advice on family planning, and referrals for additional services. The delivery of services at static clinics was supplemented by outreach visits to sex worker residences and work areas, as well as satellite clinics and mobile clinics to deliver services to hard-to-reach populations. Family planning services were integrated after sex workers expressed a need for reproductive healthcare: many had regular partners and required long-term effective contraceptive methods in addition to condoms. To achieve integration, existing protocols were modified, health providers were trained, the clinics' service delivery system was upgraded and expanded, a strong referral network was built, and community outreach activities were conducted.<sup>106</sup>

#### *Addressing SRH at VCT in Haiti*

In Haiti, PHC services have been successfully integrated into stand-alone VCT services since 1985. The centers, run by the Groupe Haitien d'Etude du Sarcome de Kaposi et des Infections Opportunistes (GHESKIO), offered diagnosis and treatment of STIs, diagnosis and treatment of tuberculosis, family planning services, ART, and MCH programs, including PMTCT. The model was rolled out to 22 public and private health centers.<sup>107</sup>

#### *Addressing the SRH needs of PLHIV in Uganda*

In Uganda, The AIDS Support Organization (TASO) began providing ART services in the town of Mbale in 2004. Although TASO offered limited family planning services to HIV patients, it lacked a comprehensive family planning program. An integration initiative was then conducted in 2006, supported by the ACQUIRE Project, to deliver more comprehensive family planning services to PLHIV. Methods delivered were condoms, oral contraceptives, injectables, and emergency contraception, with a strong referral system for longer-acting methods. Integration activities included strengthening supervision, logistics, referrals, and training; the development of a training curriculum and provider job aid on the contraceptive needs of PLHIV; supervisory checklists; improved data collection systems; the integration of family planning messages into health education materials; the orientation of HIV community workers to family planning; and the development of radio spots on family planning for dissemination in the community. In addition, advocacy was conducted with TASO managers to allow family planning activities to be conducted. Operations research found, however, several challenges to integration, including the need for further training on family planning and on dual protection; problematic referral processes; stock-outs of contraceptives; problems with record-keeping; and limited services being offered to men.<sup>108</sup>

PLHIV who desire children may also risk infection or reinfection from a partner. In developed countries, this may be prevented by using artificial reproduction techniques such as sperm washing or artificial insemination techniques. In low-resource contexts, support can include advice on conception at the fertile time of the menstrual cycle, adoption, or simple techniques to introduce sperm into the vagina using a syringe for cases where the man is HIV-negative. In cases where the male partner is HIV-infected but the woman is negative, the

situation is more complex since there is no risk-free method to ensure safe conception. Ways to help reduce risk of transmission, include attempting conception while the male partner is on ART and viral load has been reduced to undetectable levels; timing conception at the fertile time of the menstrual cycle; and using PEP for the woman.<sup>61</sup>

## Challenges and Strategies for Integration

Many programs have identified challenges when trying to deliver integrated services. They will be discussed here along with proposed strategies to achieving successful integration.

### HEALTH SECTOR COORDINATION

Health sector coordination can represent a substantial hurdle to restructuring existing service organization or integrating new service components. Administratively, the different programmatic components of SRH may come under the control of different government departments or ministries, and these separate programs and institutions may have developed their own policies, drug lists, training manuals, and technical guidelines, with little interdepartmental consultation.<sup>75,76</sup> Persistent conceptual divisions exist between SRH and STI or HIV programs, and the implementation of separate policy strategies or frameworks inhibits the delivery of linked or integrated services on the ground.<sup>30</sup> Various strategies exist to overcome these difficulties, including merging overlapping ministries, the use of cross-departmental working groups or task forces, funding cross-departmental positions, or stipulating the use of donor disease-specific funds for integrated service use.<sup>75,77,78</sup> Integration may also be supported by health sector reforms, which aim to improve service organization by reducing programmatic duplication and merging vertical programs to enhance effectiveness.<sup>79</sup>

### ORGANIZATION AND MANAGEMENT ISSUES

Health program managers at district and local levels often have to deal with the consequences of poor coordination at the national or state level, and may be squeezed between conflicting vertical and horizontal strategies.<sup>1</sup> Local managers often receive few additional resources to fund changes in service structure and little guidance on change management. Service integration can also lead to the blurring of lines of accountability.<sup>77</sup>

Furthermore, integration requires organizational change. When considering integration of STI and HIV services into PHC or SRH services, existing structures may need modification to ensure privacy for consultations, which is particularly important for the provision of sexuality counseling, STI prevention and care, adolescent healthcare, and VAW services.<sup>65,80</sup> The integration of STI prevention and care services can be undermined by a lack of resources including examination equipment, drugs and supplies, and laboratory equipment.<sup>13,16</sup> Integrated commodity supply chains can be effective, for example through joint contraceptive and condom procurement,<sup>81</sup> but may also disrupt the delivery of

effective vertical services if the efforts are not carefully planned and coordinated.<sup>82</sup>

When considering adapting current services to reach out to a broader patient base for sexual health services, the configuration of existing services may need to be considered. Delivering care to those who may be uncomfortable attending ‘women-focused’ reproductive health units (e.g., men, young people, or sex workers) may require constructing semi-specialized units or facilities to cater to their specific needs.<sup>80,83,84</sup>

A lack of effective referral systems may prevent another obstacle to delivering comprehensive SRH services. PHC services are often unable to respond to the wide range of psycho-social and clinical SRH needs of their patients, and access to specialized services is critical.<sup>85</sup> Such systems require staff to know where and how to refer patients; functioning transport systems; communications between different units and levels of healthcare; and the development of integrated information systems across the health system, for example through the use of electronic records and documentation of referral agencies.<sup>29</sup>

Another factor for consideration is how to cope with the increasing demand for counseling. Integrated, individualized SRH counseling can place heavy demands on staff time. Studies have demonstrated, however, that additional time can be made available through more efficient ways of working (e.g., task shifting) or through more structured counseling sessions which tailor the provision of information to the patient’s needs and situation.<sup>46,86</sup> Group counseling is also popular and can be used to provide information to patients before an individualized counseling session. Time invested in preventive counseling must also be balanced against significantly greater treatment costs.

### HUMAN RESOURCES AND TRAINING

Reviews of SRH integration have identified staff-related factors as important barriers to integrated service provision, including: insufficient training and motivation (linked to poor supervision and management), heavy workload and burnout, lack of incentives or compensation for increased work load, staff frustration, medical hierarchies, fear of redundancy, and territorialism among specialist staff.<sup>39,78,87</sup> Resistance to integration can be particularly strong in settings with low HIV or STI prevalence rates, where the need for integration is not understood by those working at service level.<sup>30</sup> However, in some settings, clinics may be operating below full capacity, and there may be windows of opportunity to improve efficiency and extend service coverage using existing human resources. Task-shifting is a strategy now being employed in resource-poor settings, in particular to expand human resource capacity to scale-up access to HIV care and treatment.<sup>88</sup> Initial fears over increased workloads following integration may also be allayed as providers adapt to offering additional sexual health services and appreciate the benefits of meeting patients’ needs or enhancing their own skills.<sup>31,89</sup>

At another level, healthcare providers often find it difficult to discuss sexual health and behavior, or do not appreciate the

level of confidentiality required to address sexual health issues, especially for marginalized populations. Training methodologies are required that empower providers to assess the comprehensive healthcare needs of individual patients factoring in issues such as gender, interpersonal relations, and sexuality. Providers may also need to clarify—and possibly change—their own values and attitudes. Various training courses have been developed in recent years to support programs that integrate sexuality counseling into reproductive health services.<sup>90–92</sup> Where pilot and demonstration training models have proved successful, it will be necessary to update and revise medical and nursing school curricula to ensure that preservice training incorporates new subjects and new approaches, in addition to reinforcing in-service updates.

Training also needs to support a shift from a one-way provision of information to patient-centered counseling which can support more holistic diagnosis and care.<sup>93,94</sup> In many settings, healthcare is structured around the delivery of routine tasks and care is fragmented among teams of providers.<sup>95</sup> For example, care is often focused on procedures such as weighing, taking blood tests, completing standardized history forms, or drug prescribing. Providers thus consistently miss opportunities to integrate clinical care with other services, and the wider health and social needs of patients may be neglected.

One program in the UK attempted to integrate the subspecialties of family planning and genito-urinary medicine (GUM).<sup>42,94</sup> Two possible models of integrated training were identified: (i) comprehensive dual training, leading to a “new breed of consultants”; and (ii) a modular approach—to enable those working in one speciality to provide care in the other. The former was favored by advocates of integrated services since it was felt a modular approach would result in a two-tier system, with two groups of physicians working in parallel. However, specialists felt that dual training may not equip practitioners to deal with more complicated aspects of patient care. At another level, providers also felt that a more fundamental problem was the difference in structure and culture of the specialties of family planning and GUM. Practitioners saw family planning medicine as preventive and STI medicine as generally curative; family planning was seen as community-based while GUM was hospital-based; STI counseling was seen as directly focused on treatment of disease, while family planning counseling was seen as more interactive and empathetic. Clearly these kind of differences need to be resolved before integration can be attempted.

Providers also require support from their supervisors, not only at the outset of the program but throughout the process of change.<sup>28</sup> Without such support, health workers will be unable to do their work well, and their motivation and quality of work will suffer. There is a risk, however, that as services become integrated supervisors can lose their specialized competencies, which the service providers depend upon; so careful monitoring of training and supervision needs is required.<sup>77</sup>

## PATIENT MANAGEMENT AND COUNSELING TOOLS

Vertical patient management systems can prevent effective integration. For example, separate patient registers or patient record cards for the different components of SRH care may make it impossible for one provider to cover multiple areas. Integrating data monitoring and systems tools can therefore support service integration. Another way to support integrated counseling is the provision of screening tools and job aids, such as checklists or flipcharts, which can be used during counseling, to ensure that all relevant topics are discussed. Health workers may find it easier to start talking about sensitive topics when patients are aware that there is a standard list, which makes the questions seem more routine. WHO's *Decision-making Tool for Family Planning Clients and Providers*, a contraceptive counseling tool that includes STI and HIV topics, has been shown to increase discussions on dual protection and provision of condoms during regular family planning visits.<sup>86,96</sup> A screening tool developed by the Population Council and used by both receptionists and providers has also been shown to be effective in increasing the number of services accessed per visit.<sup>47</sup>

## Conclusion

Integration of services is clearly more complex than may often seem the case, and requires careful assessment and planning to identify the most effective and cost-effective service configurations to address the different components of SRH care. While this chapter has outlined a range of service models and strategies that can be considered, it is important to emphasize that integration may not always be the best solution for certain populations or certain health problems. Conceptually, sexual health and reproductive health are two overlapping areas, but neither fully incorporates the other. As has been noted, there may also be strong cultural differences between the two subspecialties that must be addressed before trying to integrate them.

Integration does not necessarily mean that vertical service delivery and specialist disciplines will be abolished. STI programs will continue to require specialized units at secondary or tertiary levels to provide comprehensive laboratory services for testing and diagnosis, and for the treatment of complicated STI and HIV problems. This can be maintained while integrating treatment services at the PHC or secondary level. Some key target populations for STI control (e.g., men, adolescents, and sex workers) may also continue to require more specialist units due to social barriers accessing care. The implication is that referral systems between primary and specialized facilities would need to be established or strengthened, and maintained. Depending on the sociocultural context, it may also be more appropriate to address certain problems in more specialist services; care for the victims of VAW being a typical example. A symbiosis of vertical and integrated approaches is therefore recommended.

Lastly, it is worth noting that settings with a strong foundation of government-funded primary care have more success with integration than those where donor-funded vertical programs

predominate.<sup>76</sup> Therefore, one of the first steps to delivering effective integrated STI and SRH services is to ensure that PHC services are strong. Programers then need to consider the different challenges to integration that we have identified here, and develop appropriate strategies to overcome them.

# 20

## Introduction

Monitoring and evaluation are fundamental components of health programs.<sup>1–4</sup> Through these processes, program managers at all levels of the health system are able to monitor progress towards national and international goals and commitments, take corrective actions to ensure programs meet their goals, develop concrete plans based on needs, and inform program strategies.

Within the context of national STI programs, monitoring and evaluation (M&E) are critical to program strengthening, and their close epidemiological and biological ties with HIV have increased the attention paid to monitoring and evaluation of these services. However, M&E of STI control programs should stand on the merit of STIs alone as a public health priority. Emerging issues of public health concern such as the evolving resistance of *N. gonorrhoeae* to most known antibiotics put further emphasis on the need for functional systems to be in place in order to allow governments to respond to such a serious health threat.<sup>5–8</sup> This means that the traditional effects of STIs among the population could become even more serious. STIs are among the most common and curable diseases. They are recognized as a major cause of reproductive and psychological morbidities as well as facilitators of HIV transmission.<sup>9,10</sup> Fragmented and low quality program delivery and monitoring have often resulted in data being under-reported and under-utilized<sup>11,12</sup>; this in turn has resulted in limited tracking of emerging issues such as resistance. The alarming rise in resistance among some STIs to many classes of antibiotics and the absence of new medications in the pipeline mean that the health burden of STIs could significantly rise.<sup>7</sup> This rise would most likely affect developing nations more severely. It is estimated that 340 million cases of curable STIs occur per year; these include syphilis, gonorrhea, chlamydia, and trichomoniasis. Most of these occur in South and South East Asia, with sub-Saharan Africa following and finally Latin America. In total, STIs account for 17% of economic losses due to ill health.<sup>13–15</sup>

What makes monitoring and evaluating STI programs so difficult is that many infected individuals are asymptomatic, particularly among women.<sup>15</sup> This results in a gross under-reporting of cases. Compounding this is that proper diagnosis

requires a pelvic and/or rectal examination, which means that clinical settings must have access to a number of additional commodities and infrastructure such as lighting, sterilization, specula, anoscopes, and trained staff,<sup>11,15</sup> to name a few. The lack of rapid and inexpensive tests that can be used in resource-poor settings further complicates appropriate diagnosis and management.<sup>15</sup> Given that the burden of STIs is mostly in developing countries that are under-resourced in terms of commodities and human capacity, it is not surprising that most STI data are limited and so underestimate the disease burden. Those data that are available are often of questionable value and not representative of the general population.<sup>11</sup> Even with additional material resources however, there are still issues related to human capacity which must be addressed in order to improve monitoring and quality assurance within programs.<sup>16</sup>

Monitoring and evaluation have gained a renewed interest from the international community, not only for the public health issues mentioned above but also as a result of performance-based funding.<sup>17,18</sup> Increasingly, donors are requiring governments to demonstrate their performance in order to benefit from international assistance, and this implies that relevant data must be available.

In this chapter, we will focus on monitoring and evaluating STI programs. Often this is discussed within the context of national HIV program M&E but in this chapter we will focus solely on STIs. We will define monitoring and evaluation; present indicators for programs at the national and sub-national level and conclude with a discussion on how resulting data can be used at all levels of the health system (Box 20.1).

## Defining Monitoring and Evaluation

Monitoring and evaluation serve different functions within disease control programs. Together, monitoring and evaluation help program implementers to<sup>19</sup>:

- Determine the extent to which the program is on track and to make any needed corrections accordingly.
- Make informed decisions regarding operations management and service delivery.

**Box 20.1** Components of a Monitoring & Evaluation (M&E) System\*

**People, partnerships, and planning**

1. Organizational structures with M&E functions.
2. Human capacity for M&E.
3. Partnerships to plan, coordinate, and manage M&E systems.
4. National M&E plan.
5. Annual costed M&E work plan.
6. Advocacy, communications, and culture for M&E.

**Collecting, verifying, and analyzing data**

7. Routine monitoring.
8. Surveys and surveillance.
9. National and sub-national databases.
10. Supportive supervision and data auditing.
11. Evaluation and research.

**Using data for decision-making**

12. Data dissemination and use.

\*Adapted from references 20 and 21.

- Ensure the most effective and efficient use of resources.
- Evaluate the extent to which the program is having or has had the desired impact.

For STI programs, the goal of M&E should be to ensure that services are proficient in the care and prevention of STIs in terms of quality and coverage.<sup>22</sup> This implies a need to ensure that programs

are of a standard that results in efficient patient management and that services are provided to those who need them.

Indicators are used to measure progress and these are often represented in a simple input-output-outcome-impact framework (Fig. 20.1). Indicators used in monitoring and evaluation should be:

- **valid:** they measure the condition or event they are intended to measure.
- **reliable:** they produce the same results when used more than once to measure the same condition or event.
- **specific:** they measure only the condition or event they are intended to measure.
- **sensitive:** they reflect changes in the state of the condition or event of interest.
- **operational:** they can be measured with developed and tested definitions and reference standards.
- **affordable:** the cost of measuring the indicators is reasonable and within the program's financial capacity.
- **feasible:** the approach to measure the indicators is possible within the context of the program.<sup>23</sup>

Selecting the most appropriate indicators means taking into account the above standards as well as considering the program's overall goals and objectives. Objectives need to be "SMART", that is: specific, measurable, achievable, reasonable, and time-bound.<sup>9</sup>

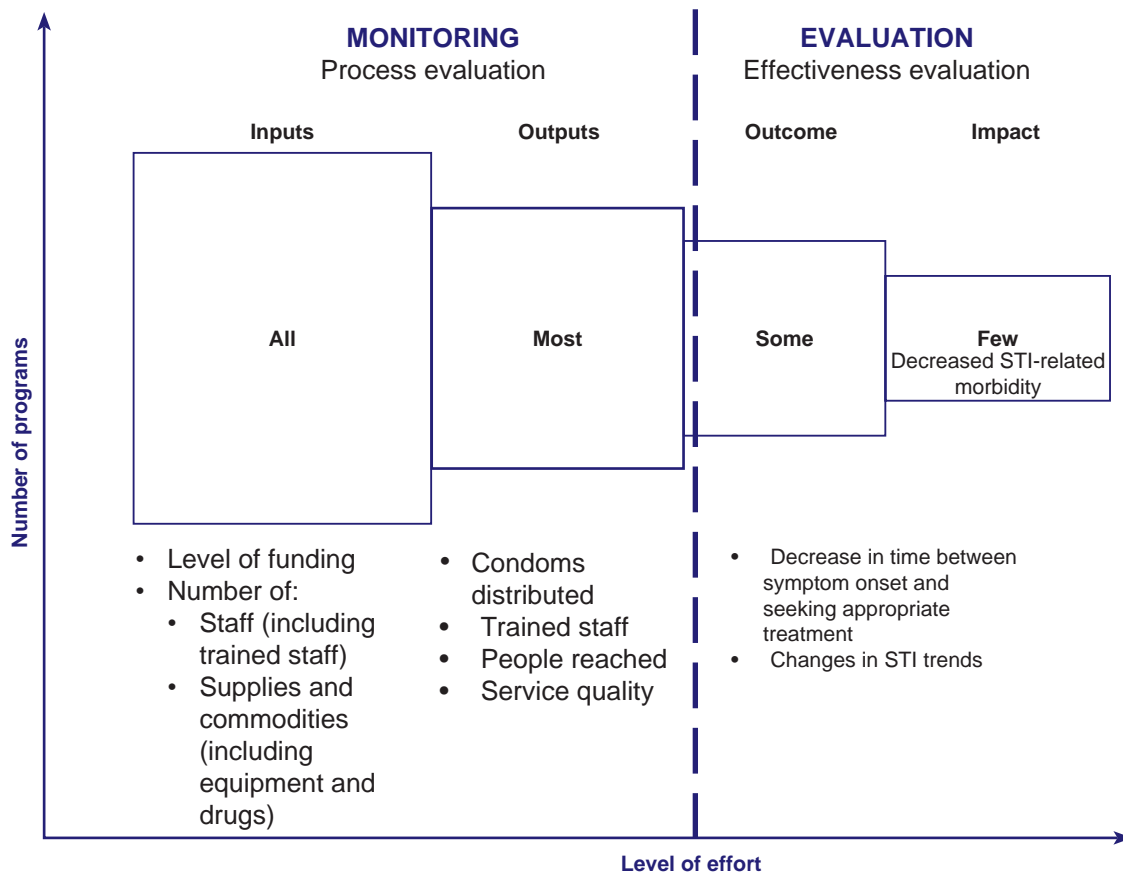

Fig. 20.1: Framework of monitoring and evaluation indicators.<sup>11,22,23,26,31</sup>

When developing STI program objectives, it is important to consider the components of a strong public health response. These include:

- Promotion of safer sex.
- Promotion of early healthcare seeking behavior.
- Introduction of prevention and care in all primary healthcare programs (including reproductive health and HIV).
- A comprehensive approach to case management that encompasses: identification of the disease/syndrome, antimicrobial treatment, education and counseling, promotion of correct and consistent condom use, and partner notification.<sup>13</sup>

Together, these components contribute to an STI control program's goals which should include reducing the rate of exposure (decreasing sexual partners and prevalence), reducing the efficiency of transmission (through safer sex behaviors such as using barrier methods such as condoms), and reducing the duration of infectiousness (through early treatment).<sup>22</sup> The identification of a program's goals and objectives is usually part of the program planning process; the indicators and processes related to the collection, management, reporting, and use of data are usually included in an M&E plan. When selecting indicators, a good rule is to collect only what will be used.<sup>24</sup>

Monitoring is defined as the routine tracking and reporting of priority information about a program and its intended outputs and outcomes.<sup>25</sup> Monitoring is a routine, or on-going, activity which aims to answer the questions "what are we doing?", "to what extent are planned activities actually realized", and "was the quality of planned activities satisfactory?"<sup>19,26</sup> Monitoring usually measures progress through the use of input and output indicators.<sup>11,23</sup> At the facility level, this generally involves keeping track of the number of people seen and treated in clinical logbooks which can then be tallied and sent for higher-level reporting. At this level, the number of indicators needing to be reported should be limited, as the clinical sites are also collecting individual patient information that is used for patient management. This means that there is a heavy recording burden at the clinic-level which can compromise data quality and use if too many data are required to be reported routinely.

At the minimum, program monitoring should include measures of:

- service delivery: number of clients served, pregnant women screened and treated for syphilis, condoms distributed, individuals referred for voluntary counseling and testing for HIV.
- quality of care: proportion of clients treated according to national (or international, in the absence of national guidance) guidelines; emerging resistance (including monitoring for treatment failure and trends in antimicrobial susceptibility).
- adequacy of staffing: patient load.
- patient response and satisfaction: total number of clients served; initial vs. repeat visits.
- capital and recurrent program costs: assess efficiency and cost-effectiveness.<sup>13</sup>

In practice, monitoring should include not only input and output indicators but measures of service quality and coverage as well. The latter two monitoring practices require periodic special studies that include provider interviews, direct observation of provider and client interactions, the use of mystery clients, reviews of clinical records, and patient exit interviews or surveys.<sup>22,24</sup>

Evaluation is defined as the rigorous, science-based collection of information about program activities, characteristics, and outcomes that determine the merit or worth of a specific program.<sup>11</sup> Unlike monitoring, evaluation occurs at specific times, usually once a program has been up and running for a specified period of time when anticipated intermediate outcomes could be expected. This is generally done in programs that are 3–5 years old<sup>27</sup>; it would be anticipated that most people for whom the services were intended would have been exposed to the program by then, making it feasible to evaluate the program outcomes. While evaluation is most often carried out at the national level to evaluate the overall response, there is also a role for evaluation at the sub-national level. At this level, evaluation is specific to the services being implemented at a site or group of sites. It focuses on the scope (what was done), the scale (what was the program's coverage), and quality. In these situations, indicators that are tailored to the activities or interventions in place are used; this differs from national-level evaluation where more standard indicators are used.<sup>26</sup>

Evaluation aims to determine whether programs are successful and how well they are achieving their overall goals and objectives. The purpose of evaluations is to influence decisions. The complexity and level of rigor of an evaluation should be based on who are the decision-makers to be influenced and the types of decisions that need to be made.<sup>27</sup> Evaluation requires an approach which looks at coverage among the population to the intervention(s), identifying those nonintervention related factors that affect outcomes, and measures of behavioral and biological outcomes.<sup>11,27</sup> Evaluation differs from research aimed at proving the efficacy or effectiveness of an approach, such as the studies that sought to demonstrate how STI control might reduce HIV incidence<sup>12</sup> or those that have demonstrated innovations in STI control program monitoring.<sup>28,29</sup> Once research demonstrates effectiveness, then these components are usually integrated into programs; these in turn are then evaluated at the national level to determine how well the response has resulted in overall reduction in STI prevalence and incidence.

Good evaluations use a mix of indicators appropriate for the different levels of the program, a combination of qualitative and quantitative approaches, and participatory approaches to design the evaluation plan.<sup>26</sup> There are several different types of evaluations including formative, process, and effectiveness (impact) evaluations. Cost-effectiveness evaluations are also important and are discussed in more detail in a later section. Process evaluations assess to what extent the planned intervention activities actually are being implemented. They assess what services are being provided, to whom, when, how often, and for what duration. Effectiveness and impact evaluations assess whether

the program made a difference. At the beginning of a program cycle, a formative evaluation (also called a formative assessment) can be done in order to collect information on the current situation in order to identify gaps and inform STI control program designers.<sup>22,30</sup>

At the national level, evaluation aims to assess the country's overall response. National-level evaluations often use surveillance data as a tool and a standard set of internationally agreed-upon indicators that allow comparability across regions and countries. The most common type of evaluation that occurs at this level is an effectiveness or impact evaluation. This type of evaluation relies heavily on biological and behavioral indicators<sup>30</sup> which are often collected as part of a country's surveillance system.

At the sub-national, or site level, evaluations are more specific to the actual activities being undertaken in that area. At this level, process evaluations are more common and these types of evaluations rely heavily on input (e.g., staff, commodities, and funding) and output (e.g., number of people treated) indicators (Fig. 20.1).

### SUB-NATIONAL LEVEL MONITORING

At the sub-national level (clinical facilities, districts, and regions), monitoring data focus mostly on monitoring a program's inputs and outputs (for example, funding, staff and people reached). The data gathered here meets three main aims: to monitor service delivery (how many people were diagnosed and treated), staff performance (are providers diagnosing and treating in line with national guidelines; what is the workload on staff), and quality of services (are people being treated effectively and with respect). These data are used to track progress towards targets but they also play an important role in ensuring that services are of good quality and respond to client needs.

At the sub-national level, healthcare facilities collect information using a wide range of tools such as patient registries, laboratory logbooks, and supply management registers. In most resource-constrained settings, data are collected on paper forms, and then consolidated into either summary (paper) forms or into electronic databases. These summary data are sent to the district level (or administrative equivalent) where they are again consolidated (with data from all facilities under the district's supervision) and sent further up the health system hierarchy. This process makes up a country's health management information system (HMIS) and serves as the backbone to inform management decisions and track progress being made at all levels of the health system.

There are several monitoring activities that take place at this level<sup>9</sup> (Table 20.1):

- Regular (monthly or quarterly) summary activity reports (from a facility to the district level, and from the district level to higher levels in the health system).
- Monthly financial reports.
- Feedback/monitoring meetings (from the facility to staff, and from the district to the facilities).
- Site visits (often as part of supervisory visits from the district to facilities).

**Table 20.1:** Examples of Common Questions, Indicators, and Data Sources for Sub-National Level Monitoring<sup>9,23</sup>

Monitoring question	Monitoring indicators	Data source(s)
Are activities carried out as planned and in a timely fashion?	Number of activities being implemented as planned	Program records
Have targets been met?	Number of people served (by age, sex)	Clinic records
How many people have been reached by the services?	Number of people served (by age, sex)	Clinic records
How many service providers have been trained in STI management?	Number of service providers trained	Program records
Is there an adequate and appropriate drug supply?	Number of drugs dispensed; number of drugs left in inventory at the end of the month; drug stockouts in the last 3 months	Commodity registers
Are the costs of the program within budget?	Expenditure vs. budget analysis	Financial records
What are the rates of specific STIs being treated?	Number of people served, by STI diagnosis	Clinic records
Is there a commodity management system in place?	Number of condoms distributed	Clinic records

- Training sessions (for all staff in facilities).
- Data analysis and management (often done at the district level, with feedback to facilities).
- Report writing and dissemination (a summary report, either paper or electronic, is compiled at the facility level; the district then compiles a similar report with summary data from all the facilities under its authority).
- Review of drug and commodity inventories (at the facility and district levels, to ensure all essential drugs are available).

As mentioned previously, an important monitoring function at the sub-national level is to monitor the quality of services, including staff performance. Unlike other monitoring data, collecting information on service quality requires that facilities and districts plan and carry out special exercises that allow for the collection of these data. Table 20.2 summarizes some of the common approaches used to collect information on service quality. At the clinic level, these exercises should inform a quality improvement process; that is, the data collected are used at this level to plan for and implement changes which will result in a stronger program.

### NATIONAL LEVEL MONITORING

Monitoring at the national level is focused around collecting, managing, and synthesizing data that come from the sub-national level and which can be used to track overall national program

**Table 20.2:** Methods to Monitoring and Assessing Program Quality and their Advantages and Disadvantages<sup>22,23</sup>

Method	Advantages	Disadvantages
Provider interviews	<ul style="list-style-type: none"> <li>• Relatively easy to carry out</li> <li>• Permits evaluating a range of knowledge</li> <li>• Standardized protocols exist</li> </ul>	<ul style="list-style-type: none"> <li>• Reporting bias</li> </ul>
Direct observation of provider	<ul style="list-style-type: none"> <li>• Transparent</li> <li>• Standardized protocol exists</li> </ul>	<ul style="list-style-type: none"> <li>• Difficult and expensive</li> <li>• Observation bias (observed provider may act differently than when not observed)</li> </ul>
Mystery client	<ul style="list-style-type: none"> <li>• Can be less expensive than provider observation</li> <li>• Less likelihood of observation bias</li> </ul>	<ul style="list-style-type: none"> <li>• Possible negative reactions to providers being observed</li> <li>• Mystery client may not have the actual clinical signs that may affect the way they are managed</li> <li>• Ethical concerns, e.g., wasting providers' time which could be used to provide real services; lack of informed consent by providers</li> </ul>
Record review	<ul style="list-style-type: none"> <li>• Avoids some observation bias</li> <li>• Less costly</li> </ul>	<ul style="list-style-type: none"> <li>• Information in records can be limited and is often inconsistent</li> </ul>
Patient exit interviews	<ul style="list-style-type: none"> <li>• Can be less expensive than direct observation</li> <li>• Less likelihood of observation bias</li> </ul>	<ul style="list-style-type: none"> <li>• Recall bias (patient may not accurately remember details of clinical procedures of counseling messages)</li> </ul>
Client satisfaction surveys	<ul style="list-style-type: none"> <li>• Can be less expensive</li> <li>• Less likelihood of observation bias</li> </ul>	<ul style="list-style-type: none"> <li>• Selection bias (those clients who select to fill in the survey may be different from other clients)</li> <li>• Recall bias (patient may not accurately remember details of clinical procedures of counseling messages)</li> <li>• Previously dissatisfied clients do not return to service and will not be sampled</li> </ul>
Quality assurance checklists	<ul style="list-style-type: none"> <li>• Relatively easy to carry out</li> <li>• Standardized protocols exist</li> </ul>	<ul style="list-style-type: none"> <li>• Requires subject matter experts to administer</li> </ul>

performance. At the national level, significantly smaller pieces of information are collected, and their availability reflects the overall function of the HMIS. These data are used to identify potential gaps in the response and inform new national plans and policies. They are used also for reporting against international goals such as the Millennium Development Goals and the UNGASS Declaration of Commitment (Table 20.3).

**Table 20.3:** Examples of Common Questions, Indicators, and Data Sources for National Level Monitoring<sup>9,23</sup>

Monitoring question	Monitoring indicators	Data source(s)
Have targets been met?	Cumulative number of people served (by age, sex)	Program records
How many people have been reached by the services?	Proportion of target population reached	Routine reports, census data, special studies
How many service providers have been trained?	Proportion of health workers trained in STI case management	Program records
Is there an adequate and appropriate drug supply?	Proportion of health facilities reporting a drug stockout in the previous 3 months	Facility survey
What are the rates of specific STIs being treated?	Proportion of clients presenting for STI management who are treated according to national guidelines	Program records, facility survey

## Evaluation

Program evaluation can occur at any level, but this depends on the purpose of the evaluation. In a previous section, we mentioned that there are generally three types of evaluation: formative, process, effectiveness (impact). The differences between these and the questions that they answer are presented in Box 20.2. At the sub-national level, evaluation can be used to assess a new approach, which can then be scaled up if found to be effective. Within the context of STI control programs, national level evaluations are relevant as they can answer the questions “What have we achieved?” (or “What outcomes are observed?”) and “What impact have we had?” (or “Does the program make a difference?”).<sup>9,19</sup> As previously mentioned, a program can be evaluated once it has “matured”, at this time it can be expected that the program has reached the majority of people it should have, hence the data needed will then be available to see if the program has achieved its outcomes and expected impact. Evaluations generally occur anywhere from 3–5 years after implementation.<sup>27</sup>

Evaluations use a mix of qualitative and quantitative methods to measure core outcome and impact indicators; surveillance also plays a key role. These indicators measure changes in societal attitudes, knowledge, and behaviors; changes in the prevalence and incidence of, as well as morbidity associated with STIs; and the overall response in terms of changes in funding and policies.<sup>26,32</sup>

There are some key limitations to the evaluations of STI control programs as these programs cannot be evaluated using traditional research approaches.<sup>26,33,34</sup> Often no baseline is available

Box 20.2 Different Evaluation Types and Examples of the Questions they Answer <sup>22</sup>	
Evaluation types and their uses:	Examples of questions that are answered by the different evaluation types:
Formative evaluation (to inform program design)	Is a program needed? Who needs the program? How should the program be carried out?
Process evaluation (monitoring overall inputs and outputs; assesses service quality)	To what extent are planned activities actually being realized? How well are the services being provided?
Effectiveness or impact evaluation (assesses outcomes and impact)	What outcomes are observed? What do the outcomes mean? Does the program make a difference?
Cost-effectiveness evaluation	Should program priorities be changed or expanded? How should resources be reallocated?

**Table 20.4:** Examples of Common Questions, Indicators, and Data Sources for National Level Evaluation<sup>22,23,26</sup>

Evaluation question	Evaluation indicators	Data source(s)
What outcomes were observed?	<ul style="list-style-type: none"> <li>Improved treatment seeking for STIs</li> <li>Prevalence and incidence of selected STIs (e.g., gonorrhea or urethral discharge syndrome) among men in past 12 months</li> <li>Prevalence of syphilis in women attending antenatal care services</li> <li>Prevalence of STIs in various sub-populations</li> <li>Decreases in symptom duration</li> </ul>	<ul style="list-style-type: none"> <li>Behavioral surveys/clinic data</li> <li>STI surveillance, STI studies</li> </ul>
Does the program make a difference?	Decreases in STI-related morbidity.	STI surveillance and clinical data, facility survey, behavioral surveillance survey (with or without biological markers)

to compare the situation before and after and, because most programs target the entire population, there are no control groups which would allow comparisons of the differences in terms of STIs between those who benefited from the program and those who did not. Additionally, the evaluation of a national program is often unable to attribute its effect to any one response, particularly in environments where multiple programs exist and overlap (as may be the case in countries where nongovernmental organizations are implementing programs). Finally, a large sample size is required to measure changes in STI prevalence which makes these evaluations expensive especially where biological markers

are needed (i.e., presence of an STI) to complement self-reported behaviors (which are prone to recall and social desirability biases).

## COST-EFFECTIVENESS EVALUATIONS

Limited resources for STI programs make selecting program components that maximize improvements in health at minimum cost an important concern. Economic evaluation aims to assure that program components and strategies are selected in a way that puts resources to their most valuable use. Evidence from cost-effectiveness analysis (CEA), the main approach to economic evaluation in health,<sup>35</sup> underlies many of the program components recommended by WHO's Global Strategy for STI Prevention and Control.<sup>36</sup> Recommendations regarding standard methods for conducting CEA for health and medical interventions have been developed by the U.S. Panel on Cost-Effectiveness in Health and Medicine, more recently the World Health Organization<sup>37</sup> and also by UNAIDS<sup>38</sup> specifically for HIV interventions. Chiou<sup>39</sup> provides a grading system for assessing CEA studies in health, which mainly focuses on methodological issues expressed in the guidelines and transparency in reporting results.

The process of developing a CEA can provide valuable insight beyond the final cost-effectiveness findings. Carrying out a CEA, the process of developing a CEA can provide valuable insight by obliging planners to clearly define resources needed to carry out an intervention, characterize the potential impacts, their value and consider which population groups would benefit and which would bear the cost; thus the CEA exercise can therefore serve to clarify objectives as well as revealing key assumptions regarding the mechanisms through which health improvements will be achieved and identify key areas of uncertainties. For example, for many interventions, levels of service regarding utilization of the services provided as well as effect or the size and or duration are not well-understood but are highly influential on CEA findings of effect.<sup>35,40</sup> As yet, although there is a growing knowledge base of CEA studies, particularly for HIV<sup>41</sup> and other STIs such as Human Papillomavirus (HPV) where new vaccines have stimulated interest in cost-effectiveness,<sup>42–45</sup> economic evaluations are still not available for many common interventions, such as behavior change communications for persons with HIV, school-based HIV prevention, abstinence programs, and prevention with most-at-risk populations in concentrated HIV epidemics, to name a few.<sup>41,46</sup> Many other interventions have evidence from only one or a few studies or countries.<sup>41,47</sup> Furthermore, CEA is seldom used by national STI control programs in decisions to adopt, scale up or eliminate program components, so that such choices are often not based on evidence of how health can be most improved with available resources available. Although crucial, cost-effectiveness is rightly viewed as just one input to STI programming decisions, along with, and secondary to, feasibility, appropriateness, acceptability, sustainability, synergies with other health programs and ethical considerations. Even under the narrow lens of economic considerations alone, Creese et al.<sup>47</sup> point out that, beyond determinations of what services

should be offered by the public sector, there are many relevant factors beyond cost-effectiveness, such as demand for services, affordability, and availability of insurance to cover the same services.

## Cost-Effectiveness Ratios

Most economic evaluations in health produce a cost-effectiveness (CE) ratio, which is expressed as a measure of benefits (i.e., health improvements) resulting from the intervention relative to the intervention's total cost ( $B/C$ ). CE ratios thus represent the health return on investment in an intervention compared with taking no action (the *null*). In contrast, *incremental cost-effectiveness ratios* (ICERs) directly compare two interventions by dividing their difference in benefits by their difference in costs, i.e.,  $(B_2 - B_1) / (C_2 - C_1)$ . WHO recommends that all studies provide CE ratios relative to the *null*, to allow comparability across studies, in addition to any ICERs presented against specific alternatives.<sup>37</sup> Both ratios reflect health benefits per unit investment (e.g., infections prevented per \$); however, this relationship can be highly sensitive to the size of an intervention due to economies of scale in costs and nonlinear epidemic dynamics. For example, the scale of HIV prevention programs explains 26–70% of cost variation across locations for similar interventions, with average cost either increasing or decreasing with the volume of services depending on the type of intervention and level of coverage.<sup>48</sup> Thus, how interventions compare with one another may differ depending on the budget available for implementation; in practice, planners should compare *net benefits* ( $B - C$ ) at scale when deciding between STI control and prevention strategies.<sup>40</sup>

## Cost Considerations

Many choices must be made when deciding what costs should be included in a cost-effectiveness analysis. All major guidelines for CEA in health and STIs<sup>35,37,38</sup> embrace the social welfare framework, which calls for accounting for all societal resources consumed by an intervention as well as all benefits resulting from the intervention. This orientation is known as the *societal perspective*. In practice, many CEAs of STI interventions take a more limited view by considering only *direct costs*. For screening or treatment services, direct costs would include personnel, equipment, medications and vaccines, diagnostic tests, physical infrastructure, overhead, as well as patient and partner travel to access services, treatment of partners and partner tracing for partner program management services. In prevention of mother-to-child HIV transmission interventions, the cost of treatment of newborns is also relevant.<sup>49,50</sup> Costs of promotion, advertising, outreach, and incentives to patients, if relevant, should also be included, as in hepatitis B virus immunization of IDUs,<sup>51</sup> or mass prevention and screening campaigns.<sup>52</sup> Additionally, costs arising from the negative health consequences of an

intervention should be considered; for example, evaluations of antenatal screening for herpes simplex virus must account for the cost associated with unnecessary cesarean deliveries.<sup>53,54</sup> *Indirect costs*, including productivity losses associated with time spent accessing services or with complications resulting from untreated infections,<sup>45,55–61</sup> are relevant to the societal perspective, but with notable exceptions,<sup>49,50,52,62</sup> most CEA of STIs do not account for them. Yet indirect costs can vary across interventions: treatment or STI management programs often require multiple consultations while a one-shot condom distribution campaign would likely consume less of participants' time. Unique among CEA guidelines, WHO advises against including patient time costs, unless they are thought to be substantial, such as in the case of accessing chronic care.<sup>63,64</sup> Thus, differences among the guidelines may explain variation in CEA methods in this respect, and limit comparability across HIV and STI cost-effectiveness studies as pointed out by recent reviews.<sup>41,45</sup> Finally, *intangible costs*, such as pain and anxiety associated with treatment side effects,<sup>37</sup> are rarely considered.

## Impact Considerations

STI programs can influence health outcomes on multiple levels, from quality of life improvements among individuals treated to averted infections and disability in newborns, partners, partners of partners, and so on. However, in practice, there is a great deal of variation in what health benefits are considered in CEA as well as how they are measured. For example, some studies of HPV immunization explore how services may impact HPV prevalence, incidence of genital warts, and cervical cancer.<sup>43</sup> Studies of screening and alternative diagnostic algorithms have examined STI cases detected or treated,<sup>43,63,65–67</sup> as well as cases of infertility, ectopic pregnancy, perinatal death or spontaneous abortion averted,<sup>66–69</sup> or simply the number of tests or correct treatments conducted.<sup>50,70</sup> In studies of HIV, the number of HIV infections prevented is often the principle outcome<sup>61,71,72</sup>; however TB cases averted and life expectancy have also been used.<sup>41,61</sup> Such variations make it difficult to assess which interventions produce most health value. Thus, the standardized summary measures of quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs), which account for years lost to premature death and years lived at different health states, are recommended,<sup>35,37,73</sup> although less frequently used.<sup>38,52,55,56,58,59,74–78</sup> When QALY or DALY measures are available to compare CE across interventions, “rule-of-thumb” thresholds are often applied, such as considering a cost below US\$50,000 per QALY cost-effective in the United States. Investigations of the value-of-life literature, however, suggest that this threshold could either overstate<sup>79</sup> or understate<sup>80,81</sup> true societal preferences for willingness to pay for health improvements. WHO recommends that interventions with a cost per QALY below the per-capita gross domestic product (GDP) be considered cost-effective.<sup>82</sup>

## Timing Considerations

Different interventions will result in different rates of costs and health benefits over time. For instance, a prevention media campaign may require a large initial investment and eventually prevent infections only some time after the intervention has been implemented, while a mass STI screening and treatment campaign is more likely to generate substantial health benefit immediately. Thus, to facilitate comparison of interventions, both costs and benefits should be expressed in *present-value* terms, with costs and benefits occurring in the future *discounted* to account for time preferences. A discount rate of 3% annually is a standard for economic evaluations in health with a reasonable range of 5–7%.<sup>35,37</sup> While CEA of STI and HIV interventions typically discount at these rates, they differ widely in their approach to analyzing the full stream of impacts over time. WHO recommends estimating all costs and benefits resulting from at least 10 years of full program implementation, noting that these impacts may extend well beyond the implementation period.<sup>37</sup> Yet, in practice, arbitrary time horizons such as 1 or 5 years following the intervention under examination are often used.<sup>37,50,59,83,84</sup> Some studies limit their time horizon more severely to completion of a diagnosis or treatment episode.<sup>61,68,72</sup> At the other extreme, more comprehensive analyses consider impacts over the lifetime of program participants. This is more often the case in evaluations of immunization, screening, or treatment interventions. Deogan<sup>52</sup> provides a rare example of a 30-year time horizon appropriately justified based on the duration of STI symptoms. Studies that do not capture the full impact of an intervention by employing a sufficiently long time horizon may claim to present a conservative analysis, but they do so at the expense of potentially underestimating efficiency in generating health improvements, thus departing from the social welfare framework and complicating comparisons of cost-effectiveness findings.

## Estimation Approach

Choice of estimation approach can also influence the extent to which costs and benefits are fully accounted for. Empirical approaches track data on participants during actual implementation, such as in Smith's<sup>70</sup> comparison of clinic- versus home-based STI screening using data from a randomized control trial. The relative cost-effectiveness of different STI diagnostic strategies is often estimated by applying multiple diagnostic algorithms onto a single group of patients presenting to a clinical setting for care and tracking correct diagnoses, treatments, and associated costs.<sup>58,68,70,85</sup> However, more often, a mathematical model is needed to combine what is known regarding epidemiological context, disease progression, intervention efficacy, behavioral parameters and other relevant information in order to project out costs and averted infections beyond what has been observed empirically. For example, Postma<sup>50</sup> used data on chlamydia prevalence, complication rates from cohort studies, diagnosis and treatment rates for STI patients and partners,

number of partners and transmission probabilities per sexual contact, reinfection rates in the absence of treatment and other parameters to estimate the cost-effectiveness of treating male partners of women screened for chlamydial infection. The most common model in CEA of STI programs is the decision tree, which defines a sequence of possible outcomes (e.g., cured vs. not cured) or states (e.g., infected vs. not infected) as “branches” over which probabilities and associated intervention outcomes are computed. Decision trees are frequently used in comparing diagnostic and treatment strategies.<sup>50,66–68,77,86,87</sup> Markov models, which define probabilities of transition between a set of mutually exclusive and exhaustive health states, are also common, for example to analyze the cost-effectiveness of routine HIV testing in the US,<sup>56</sup> viral hepatitis immunization of IDUs<sup>51</sup> and HPV screening.<sup>88</sup> Yet, all of these methods—empirical, decision trees, and Markov models—are generally unable to capture perhaps the central feature of infectious disease control: the ability of an intervention to influence population prevalence of infection by reducing infections from the population through prevention or treatment (i.e., *herd immunity*). As interventions expand, this effect can be quite powerful and can contribute to cost-effectiveness. For example, White<sup>89</sup> showed that by expanding STI diagnostic and treatment services in Britain, demand for those services would eventually decrease over time due to averted infections in sex partners of treated patients, as well as lower reinfection rates in among those treated, so that services levels could in time be reduced, forming a “virtuous circle”. *Dynamic* models—simulations,<sup>43</sup> compartmental,<sup>90</sup> and hybrid models<sup>91</sup>—can account for such effects by allowing prevalence to adjust with intervention impact.<sup>69,92</sup> However, dynamic models typically require additional data and assumptions regarding disease transmission, and perhaps for this reason comprise only a minority of CEA studies<sup>41,93</sup>; their use does appear to be growing in CEA of HPV vaccines.<sup>45</sup> As in the case of limited time horizons, estimation methods that limit consideration of impacts by failing to account for herd immunity essentially “short-change” the intervention in question by underestimating its contributions to health. As most CEA models in STIs use a static, rather than dynamic, approach, it is likely that the economic efficiency of STI interventions relative to other health interventions may be systematically undervalued through cost-effectiveness comparisons. Marra and colleagues<sup>43</sup> provide an excellent comparison of methods and assumptions used in HPV screening CEAs. More generally, Weinstein et al.<sup>94</sup> discuss the proper use of mathematical modeling for health interventions.

## Program Data for Cost-Effectiveness Estimation

Evidence regarding cost-effectiveness of STI strategies in low- and middle-income countries is scarce, although critical at both the international and national levels to guide program decisions. The WHO's Choosing Interventions that are Cost-Effective (CHOICE) initiative provides up-to-date information on

estimated costs, health impact in DALYs and cost-effectiveness of priority health interventions, which can be calibrated to specific country contexts.<sup>37</sup> Nonetheless, as the CHOICE estimates are only as good as existing evidence, STI programs should attempt to collect the necessary data to document cost-effectiveness and report estimates to improve the evidence base. At a minimum, data collected should include direct costs to the program and participants, as described above, participants' time in accessing program services to permit calculation of indirect costs and program outcomes on health and behaviors. Coupled with epidemiological data, such information can then be used to estimate total health benefits and cost-effectiveness.

## Objections to CEA in Health

Objections to CEA arise often. Neumann<sup>95</sup> suggests that in the US, there is a mistaken perception of economic evaluation as being similar to "healthcare rationing"; detractors perceive CEA as an attempt to limit provision of services when, in fact, the motivation is to get the most out of them. Others may reject the notion of collective priority-setting as wresting control from individual doctors and patients. Opponents of CEA may also simply dislike limits or the very idea of acknowledging trade-offs, which CEA attempts to make as explicit as possible to encourage informed decisions. Finally, the societal perspective can seem unrealistic compared to the real-life institutional interests faced by decision-makers.<sup>95</sup> However, Williams<sup>96</sup> argues that, while there is no perfect way to distribute limited health resources, CEA using QALYs is an attractive option. Summary health measures such as QALYs and DALYs have also been the subject of considerable ethical debate, on the grounds that measuring the value of health states cannot be done well, that utilitarianism is unethical, that such measures favor improving health in younger versus older individuals and those without versus with disabilities and out of concern that these measures intended for collective prioritization may be inappropriately utilized by physicians in clinical care.<sup>96</sup> Additional ethical perspectives on QALYs and DALYs can be found elsewhere.<sup>97–99</sup>

## The M&E Plan

An M&E plan ensures that sufficient resources are allocated to M&E activities (in terms of time, money, and human resources) to ensure that data are used in decision-making processes; and to ensure that an evidence base is created and used to demonstrate progress towards program objectives and goals. Because of the participatory process required to develop these plans, they also serve to create a culture of data demand among program planners; by participating in the M&E planning process, individuals understand the need for data and are more inclined to use it for future decision-making.<sup>19</sup> The plan should describe, in detail, both the organization and activities related to M&E including roles and responsibilities at all levels of the health system, the baselines and targets to be achieved, methods of data collection, data sources, frequency of data

collection (and the partners responsible for data collection and management), and data analysis and data use at different levels of the system. In summary, M&E plans describe how each of the 12 components of the M&E system (see Box 20.1) will be implemented and/or strengthened within the context of a national disease control strategy or plan.<sup>21</sup>

Developing an M&E plan involves several steps. These are: (i) creation of an M&E working group made up of representatives of technical partners and stakeholders involved in the STI response; (ii) review of existing plans, projects, data and past evaluation studies; (iii) identification and prioritization of indicators and M&E approaches (which should take into account internal and external M&E resources and capacity); (iv) selection of indicators and data sources (which includes looking at their feasibility); (v) development of an M&E work plan and budget; and (vi) dissemination of the plan, often through a stakeholder meeting.<sup>23,100</sup>

## DATA USE

The ultimate use of M&E data has often been considered outside the scope of monitoring and evaluation and, therefore, it is often not given sufficient attention during the design and planning of monitoring and evaluation systems. This has led to gaps in countries between the data that were collected and those which were actually used to prevent the spread of disease or improve the lives of those affected.<sup>101</sup> In some cases, data needed to perform important program functions have not been collected. In others, data were collected but never used, for example, because the data were not available in the time or format in which they were needed or because the program lacked the human or physical resources required to use them effectively. Recognizing these gaps, data use is increasingly recognized as an integral part of a monitoring and evaluation system and should be highlighted within any M&E plan.

The purposes for which data are used, and the specific data that are required to support work, vary at different levels of the health system, and from country to country. In general, however, there are three categories of use: during the delivery of services at the point of care (i.e., the health center), for health facility management, and for health system management.<sup>102</sup>

## DATA USE AT THE CLINIC LEVEL

Many of the data that are used to monitor and evaluate STI services are routinely recorded during the delivery of STI services at the facility level. These data are stored and managed in the form of individual patient records, and primarily used to inform decisions about patient/client care as well as to allow for the quality assurance process. In addition, information about the availability and consumption of resources at the health center (such as records of pharmaceuticals and other supplies distributed and in stock) is also regularly reported upwards. This information is used to ensure that health centers have sufficient resources to continue providing services, and is compared with service delivery information to forecast future resource needs.

To minimize the amount of time that healthcare workers have to spend collecting data, and to promote the best quality data, it is recommended that data that do not have a use at the recording level should not be required for reporting.

### DATA USE AT THE SUB-NATIONAL LEVEL

Oversight of health facilities may take place at different levels of the healthcare system, depending on the organization of the health system and the degree to which management has been decentralized by the government.

Regardless of whether health facility management occurs at the district, regional, or national level, key indicators (derived from aggregated data reported by multiple health facilities) are used to measure the impact on STIs (e.g., the incidence and prevalence) and the effectiveness of STI services in the geographical or political area covered. These data are compared against data about the population of the area (such as the population size, and age/sex distribution) and other epidemiological indicators (such as the percentage of a population that is expected to be at risk) to determine the extent to which services are meeting population needs.

Such monitoring data are essential for evidence-based planning and evaluation of STI programs. Information about the impact of STIs and the effectiveness of existing services allows planners and managers to prioritize the populations and settings that should be targeted, plan appropriate STI program activities for each health facility; allocate resources, and set facility-specific and program-wise goals, objectives, and targets.

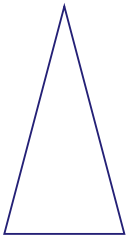

Data subsequently reported by health facilities allows managers to track the performance and improve the quality of these programs. Monitoring data are used to assess, verify, and demonstrate the success of interventions by comparing what actually happened to what was planned.<sup>103</sup> The evaluation of these data allows planners and managers to adjust programs to address weaknesses that have been identified (such as by reassigning responsibilities or reallocating resources) and to introduce and test improvement options for STI management within facilities, gradually improving the quality of services over time.<sup>17,104</sup>

These monitoring and evaluation data are used by health facility managers to highlight results and strategic lessons that can guide decision-makers and stakeholders in the overall health system.

### DATA USE AT THE NATIONAL LEVEL

Detailed information about the national STI program, including information about the populations covered by services, the resources budgeted and used, and the outcomes of STI interventions are typically aggregated at the national level.

These monitoring and evaluation data are used to inform national surveillance efforts and the national research agenda, as well as to support the management of finances at the national level. By tracking the flow of funds to service providers and other beneficiaries, and comparing them with data describing the impact

Level of data collection	Use	Data quantity
Global/Regional	Global reporting (UNGASS, MDGs)	
National	National planning and reporting	
Subnational	District planning and national reporting and planning	
Facility	Clinical team management, financial audits, and drug supply management	
Patient	Individual patient management	

**Fig. 20.2:** Monitoring and evaluation use and data quantity at different levels of the health system. UNGASS: United Nations General Assembly Special Session (on HIV/AIDS); MDGs: Millennium Development Goals.

of services, stakeholders and coordinating authorities are able to assess the cost-effectiveness of interventions and their relevance in meeting the priorities set by the national health system.

Such data are also used at the national level to demonstrate results, and areas of weakness, in support of advocacy campaigns and for mobilizing additional resources. In countries where performance-based financing has been implemented, such as in countries that have received loans from the World Bank or grants through the Global Fund to Fight AIDS, Tuberculosis and Malaria, demonstrating the outcomes of national programs is essential to sustaining the availability of health resources and maintaining services.<sup>18,105</sup>

Key indicators of the performance and impact of a national STI program are typically generated at the national level each year. In many cases, countries report data from STI programs annually to international agencies responsible for tracking progress towards achieving international goals (Fig. 20.2).

## Conclusion

Monitoring and evaluation are fundamental components of STI control programs. Within the context of decentralization and performance-based funding, as well as the increasing threat of gonococcal antimicrobial resistance, STI programs must have monitoring and evaluation systems in place that allow for the timely collection, management, and use of information.

While monitoring focuses on routinely measuring inputs and outputs, the collection of these data allows for service strengthening and may also contribute towards identifying emerging issues in a program. The added element of monitoring, measurement of service quality, allows for quality improvement processes to be put into place.

Evaluation, which is more periodic, involves the use of data from multiple sources. The complexity and expense related to carrying out a national level evaluation should be taken into account at the program planning stage in order to assure that resources are available to evaluate the medium-term outcomes or impact of the response.

## Summary

Monitoring and evaluation (M&E) are fundamental components of health programs. These activities help to inform program design, track progress being made, assure services are of the required quality, and measure the program's outcomes and impact. Emerging public health issues including antimicrobial resistance and an increased demand for data as a result of performance based funding require programs to revisit and strengthen their M&E efforts.

Monitoring and evaluation complement an STI control program's goals and objectives; they use indicators to track performance and measure change. These indicators can be broken down into an input, output, outcome and impact framework. Monitoring is defined as the routine (on-going) tracking and reporting of priority information about a program and its intended outputs and outcomes. Another important monitoring activity is measuring service quality.

Evaluation is defined as the rigorous, science-based collection of information about program activities, characteristics, and outcomes that determine the merit or worth of a specific program. Evaluations measure outcome and impact indicators. Unlike monitoring, evaluation occurs at specific times, usually once a program has been up and running for a specified period of time. Surveillance data play an important role in the evaluation of a program.

An M&E plan is needed in order to explain how the M&E system will work. These plans should include budgets to cover all M&E activities, clarify roles and responsibilities, and describe how data are managed, reported and used at all levels of the healthcare system.

## Anatomy of the Male Genital Tract

Ashini Jayasuriya • Madhur Gupta

### Introduction

The male reproductive system includes the *testes*, *epididymides*, *vas deferens*, *ejaculatory ducts*, *seminal vesicles*, *prostate*, *bulbourethral glands*, and *urethra*. The urethra is a common passage for both semen and urine. The testes are suspended in the scrotal sac by the spermatic cords. The scrotum and the penis together form the *male external genitalia*.

### Testes and Epididymides

The *testes* are paired ellipsoid bodies lying within the scrotal sac that produce male sex cells called *spermatozoa*. Each testis measures approximately 4.5 cm × 3 cm × 2.5 cm in vertical, anteroposterior, and transverse diameters, respectively. The average weight of each in adults is 10–11 g. The testes are suspended in the scrotum by the *spermatic cords*. The left testis is normally about 1 cm lower than the right. Each lies obliquely within the scrotum so that the upper pole is tilted anterolaterally.

*Efferent ductules*, 12–20 in number, emerge from the upper pole of the testis. They are highly folded and tightly packed, and unite to form the *epididymis*. The epididymis occupies the upper pole and the lateral part of the posterior border of the testis as a comma-shaped mass with an enlarged head, an intermediate body, and a tapering tail (Fig. 21.1). The head of the epididymis, formed by efferent ductules, cannot be separated from the upper pole of the testis. The body and tail are, however, easily detachable from the testis as they are bounded only by loose connective tissue. The tail of epididymis ultimately forms the *ductus (vas) deferens* which ascends along the medial part of the posterior border of the testis. The epididymis is approximately 5 cm in length in its highly folded anatomical state. If unfolded, it would be about 6 m in length. Spermatozoa are carried from the testis *via* the efferent ductules to the canal of the epididymis and subsequently continue upward via the ductus deferens.

The upper pole of the testis is connected to an embryonic remnant of the paramesonephric (Mullerian) duct called the *appendix of the testis* (Fig. 21.1). This is a small, sessile, fibro-fatty body attached to upper pole just below the head of the epididymis.

The head of epididymis itself is also attached to a pedunculated body called the *appendix of the epididymis* (Fig. 21.1). This represents the degenerated cephalic part of the mesonephric (Wolffian) duct. Between the lateral surface of the testis and the medial surface of the body of epididymis lies a semilunar recess of the cavity of the tunica vaginalis called the *sinus of the epididymis*. The anterior border of the testis is free, convex and is covered by the visceral layer of the tunica vaginalis. The posterior border is flat, broad and is related to the epididymis laterally and the vas deferens medially.

Besides the extrinsic coverings contributed by the scrotum, the testis has three intrinsic coverings formed by the visceral layers of the *tunica vaginalis*, *tunica albuginea*, and *tunica vasculosa* (Fig. 21.2). The tunica vaginalis is embryologically derived from the processus vaginalis. It consists of two layers. The visceral layer, covering the testicular surface and partially covering the epididymis, is reflected off the testis at its two poles to form the parietal layer, adherent to the internal spermatic fascia. A small amount of fluid separating the two layers allows the testis to move freely in the scrotum. Internal to the visceral layer of the tunica vaginalis lays the tunica albuginea and tunica vasculosa.

Fig. 21.1: The testis and epididymis.

**Fig. 21.2:** Schematic drawing of a horizontal section through the scrotum.

### STRUCTURE AND FUNCTION OF THE TESTES

The visceral layer of tunica vaginalis is made up of a layer of squamous mesothelial cells resembling that of the peritoneal mesothelium. The tunica albuginea is thick, dense, fibrous, and almost avascular. It projects into the interior of the testis as an incomplete vertical partition called the mediastinum testis. Numerous septa divide the testis into 200–300 conical compartments called lobules. The tunica vasculosa is made up of a fine network of blood vessels and loose areolar tissue that lines the inner surface of the tunica albuginea and the fibrous septa that delineate each lobule. Each lobule contains 1–2 seminiferous tubules, which join to form a *rete testis* in the mediastinum. From the rete testis, 10–20 efferent ductules at the upper pole pierce the tunica albuginea and form the head of the epididymis. There are 400–500 seminiferous tubules in each testis. Each tubule, when uncoiled, is about 70–80 cm long and 0.15–0.30 mm in diameter. The coiled parts are small before puberty and are lined with two types of cells—*gonocytes* and *Sertoli cells*. A third cell type, called *interstitial (Leydig) cells*, is not prominent before puberty but increases in number thereafter. After sexual maturity, under the effect of anterior pituitary hormones, the gonocytes multiply to form spermatogenic cells. The time taken for spermatogenesis is about 64–74 days. Sertoli cells are elongated polyhedral cells extending from the basement membrane to the lumen of the tubule. They have several functions including the provision of nutrition to the immature spermatozoa, maintenance of the blood–testis barrier, phagocytosis of the residual bodies formed during spermatogenesis, and they also probably act as a source of estrogenic hormones. Leydig cells are large, polyhedral cells with an eccentric nucleus having 1–3 nucleoli and scanty, but lipid-rich, cytoplasm. They are present in the connective tissue and secrete androgenic hormones which promote development of the genitalia and accessory sex glands and male secondary sex characteristics. The hormones secreted by these cells also influence general metabolism.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The main arterial blood supply to the testes is provided by the *testicular artery*, a branch of the abdominal aorta, reaching the testes *via* the spermatic cords. The *artery of the vas deferens*, a branch of the inferior vesical artery, anastomoses with the testicular artery near the testis and contributes to the blood supply. The *cremasteric artery*, a branch of the inferior epigastric artery, supplies the cremaster muscle and also anastomoses with the testicular artery near the testis. About 15–20 veins emerge from the posterior border of the testis. They form the *pampiniform plexus* which surround the vas deferens and the arteries in the spermatic cord. These empty into *testicular veins* on either side. The right testicular vein drains into the inferior vena cava at an acute angle below the level of the right renal vein. The left testicular vein drains into the left renal vein almost at right angle. The veins of the pampiniform plexus act as a counter current heat exchanger to maintain the testicular temperature a few degrees below body temperature. The testes, epididymides, and spermatic cord have a rich lymphatic supply. The lymphatics run along the testicular artery to para-aortic nodes situated adjacent to the inferior vena cava and aorta below the renal veins (Fig. 21.3). Testicular tumors metastasize to these nodes. Both testes and epididymides are supplied by sympathetic fibers from the aortic and renal plexuses via branches passing along the testicular vessels and artery of the vas deferens. Preganglionic sympathetic fibers to the testis are derived from T10 to T12 spinal segments, thus pain of testicular origin is referred to the umbilical region and lower abdominal wall. The tunica vaginalis of the testis is supplied by the genitofemoral nerve (L1–L2).

**Fig. 21.3:** Lymphatic drainage of the testes and the scrotal skin.

## APPLIED ANATOMY

The testes develop in the lumbar region and pass through the inguinal canal into the scrotum just before birth. Maldescent of a testis (*cryptorchidism*) is seen in about 3% of full-term and 30% of premature infants. Most undescended testes will descend within a few weeks of birth. Normal spermatogenesis does not occur in the undescended testes. As changes occur early, orchidopexy (surgical procedure to bring down the testis) is best performed at about 6–12 months, but certainly before 2 years of age. Malignant changes occur much more frequently in undescended testes.

Testicular tumors, although relatively rare, are one of the most common malignant tumors of young adults with a peak incidence in men aged 25–40 years (and a second peak in those over 60 years). Over 90% of testicular tumors are now curable with multimodal therapy.

*Varicoceles* (varicose veins of the spermatic cord) are nearly always left-sided and arise when the pampiniform plexus of veins is distended owing to incompetence of the valves of the testicular vein. On palpation, they are described as feeling like a ‘bag of worms.’ This swelling, best felt with the patient standing, usually disappears when the patient lies down and the scrotum is elevated. Varicoceles are generally seen in young men. Onset in older men may be associated with a renal tumor spreading to the left renal vein and consequent obstruction of the testicular vein. Right-sided varicosities may be associated with situs inversus or anomalous drainage of the testicular vein into right renal vein.

The testis can rotate around the spermatic cord within the scrotum. Torsion of the testis is often associated with a large tunica vaginalis. Torsion commonly occurs in young men and children and is accompanied by severe pain. If treatment is delayed, the arterial supply may be occluded followed by death and necrosis of testicular tissue. The testicular appendix may also undergo torsion causing acute testicular pain that may be mistaken for a testicular torsion.

## SPERMATIC CORD

Spermatic cords suspend each testis in the scrotum. Each begins at the deep inguinal ring, passes through the inguinal canal, emerges through the superficial inguinal ring and descends in the scrotum to end at the posterior border of the testis. Within the coverings of the cord are the ductus (vas) deferens, the testicular artery, the artery of the ductus deferens, the cremasteric artery, the pampiniform plexus of veins, autonomic sensory nerves, and the genital branch of the genitofemoral nerve. Lymphatic vessels draining the testes are also found within the spermatic cord.

## Ductus Deferens

The *ductus deferens* transports spermatozoa from the testis to the prostatic urethra. It is approximately 45 cm long and has a thick muscular wall with a narrow lumen. It commences as a continuation of the tail of the epididymis and ascends along the posteromedial side of the testis and through the inguinal

**Fig. 21.4:** Section through the prostate gland, demonstrating the passage of the ductus deferens and its connections within the prostate.

canal as a part of the spermatic cord. At the bladder base, it passes medial to the seminal vesicle. It then dilates to form the *ampulla of the ductus deferens*. It joins the duct of the seminal vesicle at an acute angle to form the *ejaculatory duct*, which passes through the parenchyma of the prostate and opens on either side of the prostatic utricle on the *colliculus seminalis* of the prostatic urethra (Fig. 21.4).

## STRUCTURE AND FUNCTION

The wall of the ductus deferens consists of four layers; (from outside inward) the *adventitia*, the *muscular layer*, the *lamina propria*, and the *epithelium*. The epithelium consists of pseudostratified columnar cells with long regular microvilli (stereocilia). The cells are considered to have some secretory functions, especially in the abdominal and prostatic segments. The muscle coat is made up of three layers: inner and outer longitudinal and in between, circular smooth muscle. The contractions of the muscular wall transport of spermatozoa to the prostatic urethra.

## BLOOD SUPPLY AND INNERVATION

The ductus deferens has its own artery, usually derived from the superior vesical artery which anastomoses with the testicular artery. The venous drainage is supplied by corresponding arteries. The nerves of the ductus deferens are derived from the inferior hypogastric plexus. It has a rich innervation of sympathetic nerve fibers, which enable rapid contraction and expulsion of sperm during ejaculation.

## APPLIED ANATOMY

Bilateral *vasectomy* is performed under local anesthesia as a permanent method of contraception by dividing the vas deferens between ligatures. Spermatozoa may be present in the first few postoperative ejaculations. Afterwards, only the secretions of the seminal vesicles and prostate constitute the ejaculated seminal fluid. Vasectomy is an effective form of contraception with a low failure rate of 1:2000.

## Seminal Vesicles

Seminal vesicles are paired accessory sex glands, approximately 5 cm in length, embedded in connective tissue on the posterior surface of bladder. When uncoiled, each is 10–15 cm in length. The wider, blind end of the vesicle lies behind the ureter and joins the vas deferens just above the base of the prostate by means of its ejaculatory duct. These begin just above the base of the prostate, are about 2 cm long, and lie almost completely within the prostate. They course obliquely forward, medially, and downward to converge at the prostatic urethra where they open at the *colliculus seminalis* (Fig. 21.4). The seminal vesicles drain the seminal fluid into the prostatic urethra.

### STRUCTURE AND FUNCTION

The seminal vesicles have an external connective tissue coat (adventitia), a thin muscle coat, and an inner mucous coat. The muscle coat has outer longitudinal and inner circular layers of smooth muscle fibers. The mucosal layer is made of simple columnar secretory epithelium with apical microvilli. It is thrown into many folds. Some goblet and stem cells are also present. The seminal vesicles are mainly secretory in function and their secretory products make up 70% of the seminal fluid. These products include potassium ions, fructose, prostaglandin, endorphin, fibronectin, carbonic anhydrase, transferrin, and sperm motility factors. These are concerned with the modification of the motility of sperm. These products also make the semen alkaline. The walls of the seminal vesicles contract during ejaculation and expel their contents into the ejaculatory ducts.

### BLOOD SUPPLY AND INNERVATIONS

The arterial supply of the seminal vesicles is from the inferior vesical and middle rectal arteries. Draining veins follow the arteries. The nerve supply to the seminal vesicles is from the hypogastric autonomic plexus. The secretory activity is regulated primarily by cholinergic fibers from the pelvic splanchnic nerves and testosterone.

### APPLIED ANATOMY

When swollen or inflamed, the seminal vesicles become tender on palpation during rectal examination. An abscess here may rupture into the peritoneal cavity. The seminal vesicles contract a little earlier than the vas deferens during sympathetic stimulation for ejaculation. Hence, the first part of the ejaculate is mainly the secretion from the seminal vesicles with few spermatozoa.

## Prostate

The prostate gland is composed of glandular and fibromuscular tissue surrounded by a thin dense fibrous capsule (true capsule) and an outer, loose sheath of pelvic fascia (false capsule). It is traversed by the urethra and comprises apex, base, anterior, posterior, and two inferolateral surfaces. The prostate is approximately 4 cm

in transverse diameter at the base, 3 cm in vertical diameter, 2 cm anteroposteriorly, and usually weighs about 8 g. The apex is directed downward and lies on the upper surface of the urogenital diaphragm. The base is directed upward and is closely related to the neck of the bladder. The urethra enters the gland by piercing the base in the midline at the junction of its anterior one-third and posterior two-thirds. It passes vertically downward from the base to the apex, and exits the gland through its anterior surface just above and in front of the apex (Fig. 21.5 a and b).

The prostate is divisible into lobes. The two lateral lobes are separated posteriorly by a shallow median groove. Because these lobes are often fused, they are sometimes known as the posterior lobe. Superiorly on the posterior surface, a transverse groove between the entry points of the two ejaculatory ducts represents the median lobe of the prostate. The anterior lobe is the fibromuscular isthmus joining the two lateral lobes in front of the urethra (Fig. 21.5a).

Two ejaculatory ducts pass posterolaterally to the median lobe and open at the colliculus seminalis. A diverticulum from this part of the prostatic urethra, the prostatic utricle, extends upward and backward for about 6 mm from the centre of the colliculus seminalis (Fig. 21.5b).

**Fig. 21.5:** (a) Sagittal section through the prostate gland. (b) Coronal section through the prostate gland demonstrating the structures within the gland.

## STRUCTURE AND FUNCTION

The moderately thick stromal connective tissue, forming the true capsule, surrounds and supports the glandular element of the prostate. A condensation of endopelvic fascia forms the false capsule. It blends anteriorly with the puboprostatic ligaments. Below, it blends with the superior layer of the urogenital diaphragm and the perineal body. Posteriorly the false capsule blends with the rectovesical fascia of Denonvilliers. The space between the true and false capsules contains the prostatic venous plexus (Fig. 21.5a).

About a quarter of the prostatic mass is muscle tissue, another quarter is connective tissue, and remaining half is secretory glandular tissue. The glandular elements are composed of secretory follicles lined by simple columnar epithelium. The glands are embedded in the fibromuscular part and are arranged more or less concentrically in three layers around the urethra. The mucosal glands in the periurethral tissue are the smallest, open at various points around the lumen of the urethra, and may form adenomatous nodules (usually in older age). The second layer is that of submucosal glands. The external, 'true' prostatic glands have tubuloalveolar secretory units and are located in the outermost part of the gland. The normal glandular activity of the prostate is controlled by androgens. Prostatic secretion, a thin, milky fluid, is discharged into the prostatic urethra by contraction of smooth muscle in the prostate. Prostatic secretions provide approximately 20% of the volume of seminal fluid and contain citric acid and acid phosphatase.

## BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND NERVE SUPPLY

Branches from the *inferior vesical*, *middle rectal*, and *internal pudendal arteries* supply the prostate. The veins draining the gland form a plexus in the space between true and false capsules. This venous plexus receives the *deep dorsal vein of the penis* and communicates with the *vesical venous plexus*. From this plexus, veins pass along the posterior ligament of the bladder into the internal iliac veins. The prostatic venous plexus also communicates with the extradural internal vertebral venous plexus through the anterior sacral foramina. During coughing and sneezing or abdominal straining, it is possible for prostatic venous blood to flow in a reverse direction and enter the vertebral veins. This explains the frequent occurrence of skeletal metastasis in the lower vertebral column and pelvic bones of patients with carcinoma of the prostate. Cancer cells enter the skull via this route by floating up the valveless prostatic and vertebral veins. Lymphatic vessels from the prostate pass mainly to the internal iliac and sacral lymph nodes. A few lymphatics may drain into the external iliac lymph nodes. The prostate is richly supplied with sympathetic and parasympathetic nerve fibers. The former are derived from the inferior hypogastric plexus and the latter from the pelvic splanchnic nerves (S 2, 3, and 4). Pain due to prostatitis hence tends to be referred to the perineum.

## APPLIED ANATOMY

The prostate can be examined clinically by performing a *digital rectal examination*. The examiner's gloved index finger is placed in the anal canal and rectum. This allows for the posterior surface of the prostate to be felt through the anterior rectal wall. The following structures can also be palpated by this examination. Anteriorly, opposite the terminal phalanx are the contents of the rectovesical pouch, the posterior surface of the bladder, the seminal vesicles, and the vas deferens. Opposite the middle phalanx are the rectoprostatic fascia and the prostate, and opposite the proximal phalanx are the perineal body, the urogenital diaphragm, and the bulb of the penis (Fig. 21.6).

Trace amounts of proteins produced specially by prostatic epithelial cells are found in the peripheral blood. In certain prostatic diseases, notably cancer of the prostate, this protein appears in the blood in increased amounts. The *prostatic specific antigen* test measures these protein levels.

In prostatic operations, the prostatic venous plexus poses a risk of severe hemorrhage, being thin-walled, valveless, and draining directly into larger internal iliac veins.

*Benign hyperplasia* of the prostate is common in older men, particularly after the age of 50. The median lobe of the gland enlarges upward and encroaches on the sphincter vesicae at the neck of the bladder. The leakage of urine into the prostatic urethra causes an intense reflex desire to micturate. The enlargement of the median and lateral lobes of the gland produces elongation and lateral compression and distortion of the urethra (ball-valve effect) so that the patient experiences difficulty in passing urine and the stream is weak. The enlargement of uvula vesicae due to an enlarged median lobe results in the formation of a pouch of stagnant urine within the bladder which may become infected.

Owing to the relationship of the prostate to the prostatic urethra, urethral obstruction may be relieved by a *transurethral*

**Fig. 21.6:** Sagittal section demonstrating the anatomical relationship of the male pelvis.

*resection of the prostate.* Partial or complete removal of the prostate is called *prostatectomy*.

## Scrotum

The scrotum is an outpouching of the lower part of anterior abdominal wall and contains the testes, epididymides, and lower part of the spermatic cord. It develops embryologically from two outpouchings of the anterior abdominal wall called *labioscrotal swellings* which fuse in the midline. The *median subcutaneous raphe* divides the scrotum into the right and the left halves.

The wall of scrotum has the following layers from outside inward: the skin, the dartos muscle continuous with the superficial fascia (Colles') of the perineum, external spermatic fascia derived from the external oblique muscle, the cremasteric fascia derived from the internal oblique muscle, and the cremaster muscle. Internal to this lies the internal spermatic fascia derived from the fascia transversalis and the parietal layer of tunica vaginalis (Fig. 21.2).

Scrotal skin is darker and rugose. It contains numerous sebaceous and sweat glands with scattered coarse hairs that appear after puberty. The evaporation of sweat helps to lower the scrotal temperature. The skin, being adherent to the underlying dartos muscle, becomes corrugated when this muscle contracts, especially in children, young adults, and in cold temperature. There is no subcutaneous adipose tissue in the scrotum. Edema, secondary to cardiac or renal failure, tends to collect within the scrotum, as it is a suspended organ and the skin is lax and stretches easily.

## BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The scrotum is supplied by perineal branches of the internal pudendal arteries, the superficial and deep external pudendal branches of the femoral artery, and the cremasteric branch of inferior epigastric artery. The scrotal veins accompany the arteries and drain partly into the internal iliac and partly into the great saphenous vein. Arteriovenous anastomoses promote heat loss, thus assist in the control of the temperature of the testis which is important for spermatogenesis. Lymph vessels from the wall of the scrotum drain into the medial group of superficial inguinal lymph nodes (Fig. 21.3). Sensory supply to the anterior third of the scrotum is from the L1 spinal segment via the genitofemoral and ilioinguinal nerve. The genitofemoral nerve also supplies to the cremaster muscle. The sensory supply to the posterior two-thirds is from S3 and S4 spinal segments via the posterior scrotal branches of pudendal nerve and the perineal branch of the posterior cutaneous nerve of the thigh (posteroinferior scrotum). The dartos muscle is supplied by sympathetic nerves from the superior hypogastric plexus.

## Penis

The penis is the male organ of copulation and the outlet for semen and urine in a male. It consists of three parallel, cylindrical

**Fig. 21.7:** Cross-section through the penis demonstrating erectile tissue and blood supply

bodies of erectile tissue enclosed in a fibrous capsule called the tunica albuginea (Fig. 21.7). Superficial to this is a tubular sheath of fascia called the deep fascia of the penis (Buck's fascia). The two dorsally placed *corpora cavernosa* are attached to the sides of the pubic arch. They diverge in the perineum to form the *crura* of the penis but are fused together in the body of the penis. The *corpus spongiosum* lies on the ventral (urethral) surface between the corpora cavernosa and transmits the urethra. Proximally, it is enlarged to form the *bulb* of the penis and is attached between the crura to the inferior layer of the urogenital diaphragm. Distally, it expands to form the glans penis into which the tapered ends of the corpora cavernosa are inserted (Fig. 21.8).

The urethra traverses the glans and opens through as a vertical slit, the *external urethral orifice*. The glans penis is conical in shape. The margin of its base projects outward and is called the corona of the glans. The glans has a higher concentration of sensory nerve endings than the rest of the body of the penis. The cavernous erectile tissue of which the corpora are composed consists of intercommunicating spaces which are separated by fibrous trabeculae and are filled with blood during penile erection.

**Fig. 21.8:** The male penis.

The skin of the penis is delicate, elastic, and hairless except at the base. It is freely movable over the surface and distally forms a free fold (or double layer) called the *prepuce*, which extends over the glans for a variable distance and allows for the collection of secretions of the preputial glands called smegma. In the midline, a narrow, free fold of skin (the *frenulum of the prepuce*) passes from the urethral surface to the deep aspect of the prepuce.

The superficial fascia of the penis is composed of loose areolar tissue without fat. The deep fascia forms a close fitting sheath around the corpora. The penis is supported by the fundiform ligament and the suspensory ligament. The latter is a fibroelastic structure, which spreads out from the anterior surface of the pubic symphysis to fuse with the deep fascia on the dorsum and sides of the penis. The dorsal vessels and nerves lie deep to it. The fundiform ligament arises from the membranous layer of the subcutaneous tissue of the lower abdomen.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND NERVE SUPPLY

The arterial supply to the corpora is provided by the *deep arteries of the penis*. The corpus spongiosum is also supplied by the *artery of the bulb*. The skin of the organ is supplied by the *dorsal artery of the penis*. All the above arteries are branches of the internal pudendal arteries which themselves arise from the internal iliac arteries (Fig. 21.9). The deep arteries are the principal supply to the cavernous spaces in the three corpora during erection. They give off numerous branches which open directly into the

cavernous spaces, called *helicine* arteries. The venous drainage from the cavernous spaces is by means of a venous plexus which joins the deep dorsal vein located in the deep fascia. This in turn drains into the prostatic plexus of veins by passing below the symphysis pubis. The superficial coverings of the penis drain into the superficial dorsal vein which lies in the superficial fascia. It divides proximally into right and left branches, which pass into the external pudendal veins. The lymphatic drainage of the penile skin is into the medial group of superficial inguinal nodes. The deep structures drain into the internal iliac nodes. The lymphatic drainage of the glans is directly into deep inguinal nodes. The innervation of the penis is supplied by the pudendal nerve via the dorsal nerve of the penis and autonomic nerves from the inferior hypogastric plexus. The skin covering the root of the penis is supplied by the ilioinguinal nerve, the perineal branches of the posterior cutaneous nerve of the thigh, and the posterior scrotal branches of the perineal nerve.

### APPLIED ANATOMY

Following erotic stimulation, smooth muscle in the fibrous trabeculae and the walls of the helicine arteries undergo relaxation due to parasympathetic stimulation. As a result these arteries, which are coiled in the flaccid state, straighten and their lumina enlarge allowing blood to flow into the cavernous spaces. The bulbospongiosus and ischiocavernosus muscles compress the venous plexuses at the periphery of the corpus cavernosa, to prevent venous return. The corpora therefore enlarge and the penis becomes erect. Detumescence takes place post ejaculation, where secondary to sympathetic stimulation, smooth muscle in the helicine arteries constrict, and the bulbospongiosus and ischiocavernosus muscles relax, allowing the cavernous spaces to empty and the penis to return to the flaccid state.

*Circumcision* is the surgical removal of the prepuce. This may be done for religious or hygiene reasons. There is now accumulating evidence that circumcised individuals may be less susceptible to certain types of viral sexually transmitted infections including HIV and HPV as compared to their uncircumcised counterparts.

### Male Urethra

The male urethra is about 20 cm long and extends from the neck of the bladder to the external meatus on the glans penis. It is divided into three parts, namely, *prostatic*, *membranous*, and *penile*.

The prostatic urethra is 3 cm long. It passes from the internal urethral orifice at the apex of the trigone of the bladder through the prostate, to reach the urogenital diaphragm, at which point it continues as the membranous urethra. It is the widest and most distensible portion of the urethra. On the posterior wall is a longitudinal ridge called the urethral crest or *verumontanum*. On either side of this ridge, there is a groove called the prostatic sinus into which the prostatic glands open. On the summit of the urethral crest is a depression, the prostatic utricle, which is

Fig. 21.9: Arterial supply of the male external genitalia.

**Fig. 21.10:** The longitudinal section of the penis to demonstrate the urethra and associated structures by schematic diagram.

analogous to the uterus and vagina in the female. On the edge of the mouth of the utricle are the openings of the two ejaculatory ducts (Fig. 21.10).

The membranous urethra is about 1–2 cm long and lies within the urogenital diaphragm surrounded by the sphincter urethrae muscle. Distally, it is continuous with the penile urethra. It is the shortest and least dilatable portion of the urethra (Fig. 21.10). The sphincter urethrae surround the urethra in the deep perineal pouch. It arises from the right and left pubic arch and passes medially on the posterior surface to encircle the urethra. It is supplied by the perineal branch of the pudendal nerve. The muscular sphincter which compresses the membranous part of the urethra relaxes during micturition. Contraction of this muscle allows for micturition to be voluntarily stopped.

The penile urethra is about 15 cm long and is enclosed in the bulb and the corpus spongiosum of the penis. The bulbourethral glands open into the penile urethra below the urogenital diaphragm. Within the bulb, the urethra is dilated to form the intrabulbar fossa and within the glans, to form the navicular fossa. The penile urethra ends at the external urethral meatus. This is the narrowest part of the entire urethra (Fig. 21.10).

### Bulbourethral Glands

The two bulbourethral glands are yellowish, rounded, pea-sized, glandular masses within the deep perineal pouch. They lie on either side of the membranous urethra, above the perineal membrane and bulb of the penis in the deep perineal pouch and are enclosed by fibers of the sphincter urethrae. They gradually diminish in size in older age. The duct of each gland passes obliquely forward through the perineal membrane, and empties secretions into the penile urethra about 2.5 cm below the perineal membrane. The bulbourethral glands contain tubuloalveolar cells producing mucoid substances. These secretions have been shown to contain a

number of enzymes including  $17\beta$  hydroxysteroid dehydrogenase. Nerve fibers sensitive to vasoactive intestinal polypeptide have been observed around the secretory units. Diffuse lymphoid tissue and intraepithelial lymphocytes, monocytes, and macrophages are also present in these glands which help in combating infections. Secretions are poured into the urethra during the parasympathetic stimulation associated with erection.

## Anatomy of the Female Genital Tract

Ashini Jayasuriya • Madhur Gupta

### Introduction

The female *genitalia* or genital organs consist of internal and external structures. The internal genitalia, situated within the lesser pelvis, are the ovaries, uterine tubes, uterus, and vagina. The external genitalia lying in front and below the pubic arch are the mons pubis, labia majora, labia minora, pudenda, clitoris, bulb of the vestibule, and greater vestibular glands.

### Ovaries

Ovaries are paired, almond-shaped organs homologous to the testes in men. In nulliparae, the ovaries are pinkish white structures, measuring 2–4 cm in length, 1.5 cm in width, and 1 cm in thickness. Each ovary is attached to the posterior surface of the *broad ligament* by a peritoneal fold called the *mesovarium* (Fig. 22.1a). The part of the broad ligament extending between the attachment of the mesovarium and the lateral wall of the pelvis is called the *suspensory ligament* of the ovary. The ovary is connected to the lateral margin of the uterus by the *round ligament of the ovary* or *ovarian ligament*.

The ovary usually lies against the lateral wall of the pelvis in a depression called the *ovarian fossa*, bounded above by the external iliac vessels, in front by the obliterated umbilical artery, and behind by the ureter and internal iliac vessels. The peritoneum of the floor of the fossa separates the ovary from the underlying obturator nerve and vessels. The surface of the ovary is not covered by the peritoneum, hence during ovulation the oocyte is expelled into the peritoneal cavity. The oocyte is then trapped by the *fimbriae* of the *uterine tube* and carried to the ampulla. The ovary is kept in position by the broad ligament and mesovarium. After pregnancy, the broad ligament may become lax and the ovary may prolapse into the rectouterine pouch (pouch of Douglas). In these circumstances, the ovary may be tender and cause discomfort on sexual intercourse (*dyspareunia*). An ovary situated in the rectouterine pouch may be palpated through the posterior fornix of the vagina.

**Fig. 22.1:** (a) Lateral view of the uterus and ovary, demonstrating the structures which lie within the broad ligament. (b) Structure of the uterus and uterine tubes.

## BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The *ovarian arteries* arise from the abdominal aorta at around the first/second lumbar vertebrae and reach the ovaries after descending along the posterior abdominal wall, crossing the external iliac vessels at the pelvic brim and passing through the ovarian suspensory ligaments. Before anastomosing with the *uterine artery*, a branch of each ovarian artery passes through the mesovarium to supply its respective ovary. The right *ovarian vein* drains into the inferior vena cava at an acute angle. The left ovarian vein drains into the left renal vein almost at a right angle. Lymphatic vessels follow the ovarian vessels and drain into *pre-aortic* and *para-aortic lymph nodes*. Nerve fibers descend along the ovarian vessels from the ovarian plexus that communicates with the uterine plexus. Sympathetic preganglionic fibers are derived from T10–T11 segments of the spinal cord. Parasympathetic fibers are derived from the *vagus nerve*. Afferent fibers from the ovaries reach the central nervous system from the dorsal route of the T10 spinal nerve.

## FUNCTIONS

The ovaries have two interrelated functions: the production of *gametes (oogenesis)* and the production of *steroids (steroidogenesis)*. Developing gametes are called oocytes, and post-ovulation, are called ova. The major groups of steroid hormones secreted by the ovaries are *estrogens* and *progestogens*. The estrogens promote growth and maturation of internal and external sex organs and are responsible for the typical female characteristics that develop at the time of puberty. They also act on the mammary glands to promote breast development, by stimulating ductal and stromal growth and the accumulation of adipose tissue. The progestogens prepare the internal sex organs, mainly the uterus, for pregnancy by promoting secretory changes in the endometrium. They also promote lobular proliferation of mammary glands for lactation. Both groups of hormones play an important role in the regulation of the menstrual cycle by preparing the uterus for implantation of the fertilized ovum. If implantation does not occur, the uterine endometrium undergoes degeneration and is shed as menstruation.

## APPLIED ANATOMY

Inflammation of an ovary may produce localized peritonitis of the ovarian fossa and irritation of the obturator nerve.

At ovulation, some women experience paraumbilical pain called '*mittelschmerz*' due to pain referred to the T10 dermatome.

On the right hand side, the vermiform appendix in some women lies close to the ovary and uterine tube. A ruptured tubal ectopic pregnancy may therefore be misdiagnosed as acute appendicitis.

Follicular cysts are common and originate from unruptured graafian follicles. They rarely exceed 1.5 cm in diameter. Luteal cysts are formed in the corpus luteum due to fluid retention preventing the corpus luteum from becoming fibrosed. Luteal cysts rarely exceed 3 cm in diameter.

Polycystic ovarian disease (Stein–Leventhal syndrome) is characterized by bilateral enlarged polycystic ovaries. Although the pathogenesis is not clear, it may be caused by abnormal levels of different steroid hormones.

A wide mesovarium and long suspensory ligament predispose to torsion of the ovary. Torsion is a complication in 10–20% of cases of ovarian tumor.

## Uterus

The uterus in a non-pregnant woman is shaped like inverted pear and is a thick walled, hollow, muscular organ. It is normally situated in the lesser pelvis between the urinary bladder and the rectum. On average, the uterus is 7–8 cm long, 5–7 cm wide, and 2–3 cm thick. The uterus consists of two major parts: an upper muscular part, the *body*, and a lower fibrous part, the *cervix*. Between these two lies the *isthmus*, a slightly constricted fibromuscular region corresponding to the *internal ostium* (Fig. 22.1b). Before puberty the uterine body and the cervix are approximately equal in length, but in adulthood the body enlarges to a ratio of 2:1 or 3:1. The rounded upper part of the body that lies above the entrance of uterine tubes at the cornu of the uterus is known as the *fundus* of the uterus.

The cervix is about 2.5 cm long and for descriptive purposes, can be divided into a *supravaginal* and a *vaginal* part. The vaginal part projects through the anterior wall of the upper part of the vagina, communicating with the vagina through the *external ostium* of the uterus. This opening is small and rounded in the nulliparous state, but in multipara may resemble a transverse slit, thus producing an anterior and a posterior cervical lip. The supravaginal part of the cervix, which expands greatly in pregnancy after about 24 weeks of gestation, forms the lower uterine segment, through which cesarean section can be performed. The supravaginal part of the cervix is surrounded by visceral pelvic fascia, often referred to as the *parametrium*. It is in this fascia that the uterine artery crosses the ureter on each side of the cervix.

The uterus normally projects superioanteriorly over the urinary bladder, i.e. bending forward at a right angle to the vagina—*anteversion*—and bending forward on the cervix—*anteflexion*. In 20% of individuals, the uterus is bent backward relative to the vagina—*retroversion*. If also bent backward, it is additionally described as being *retroflexed* (Fig. 22.2).

Fig. 22.2: Common positions of the uterus.

**Fig. 22.3:** Anatomical relationships within the female pelvis.

In the anteverted and anteflexed position, the body of the uterus is related anteriorly to the *vesicouterine pouch* and the superior surface of the urinary bladder. Here the peritoneum is reflected from the uterus onto the posterior surface of the bladder. As the ureters pass forward to enter the bladder, they lie in proximity to the supravaginal cervix. The body of the uterus is related posteriorly to the *rectouterine pouch* (*pouch of Douglas*) which separates it from the sigmoid colon. The inferior part of this pouch is closely related to the posterior vaginal fornix (Fig. 22.3). Lateral to the body of the uterus lie the broad ligament and the uterine vessels. The round ligament of the uterus is attached just behind the entrance of the uterine tube into the cornu of the uterus. The broad ligaments are two-layered folds of the peritoneum that extend across the pelvic cavity from the lateral margins of the uterus to the lateral pelvic walls.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The *uterine arteries* are branches of the internal iliac arteries. They run downward, forward, and medially across the levator ani muscle and then, at the base of the broad ligament, cross anterior to and above the ureters, about 2 cm lateral to the vaginal fornix. Having crossed over the ureter, each uterine artery passes upward along the lateral margin of the uterus, between the two layers of the broad ligament, supplying the uterus and uterine tube and anastomosing with the ovarian artery. At the isthmus, each gives off a descending branch that supplies the cervix and vagina. Part of the blood supply to the uterus is also supplied by the *ovarian arteries*, arising from the abdominal aorta (Fig. 22.1b). The *uterine veins* enter the broad ligaments alongside their arterial counterparts and form a *uterine venous plexus* on either side of the cervix which subsequently drains into the internal iliac veins. The uterine venous plexus is also connected to the superior rectal vein, forming a *portal-systemic anastomosis*. The majority of lymphatic vessels from the fundus of the uterus drain into the *pre- and para-aortic* group of lymph nodes. A few lymph vessels from the lateral angles run along the round ligament to drain into the medial group of the *superficial inguinal lymph nodes*. Lymphatic vessels from the upper parts of the uterine body enter the *external iliac lymph nodes* and lymphatics along the lower uterine body and

the cervix enter the *internal iliac and sacral lymph nodes*. There is also a *paracervical lymph node* along the side of the cervix in the connective tissue which may be the first node to be involved in the spread of cancer of the cervix. The uterus is richly supplied by sympathetic (T12–L1) and parasympathetic nerves (S2–4) through the inferior hypogastric and ovarian plexuses. Sympathetic innervation results in uterine contraction and vasoconstriction. The parasympathetic nerves inhibit uterine contractions and lead to vasodilatation. These effects are, however, complicated by the pronounced effects of hormones on the genital tract.

Painful stimuli from the uterine body pass through the sympathetic nerves to the spinal cord and presacral neurectomy may relieve pain in cases of spasmodic dysmenorrhea, not relieved by other means. Pain sensations from the cervix and upper vagina are conveyed predominantly *via* the parasympathetic nerves to S2–4 spinal segments.

### UTERINE SUPPORTS AND LIGAMENTS

The uterus is maintained in position by condensations of the pelvic fascia known as the *transverse cervical ligaments*, the *pubocervical ligaments*, and *uterosacral ligaments*. The principal support of the uterus is, however, the *pelvic floor* (pelvic diaphragm) which is composed of the two levator ani and the two coccygeus muscles. The muscles of the urogenital diaphragm and the perineal body provide further support for the uterus, hence damage to the perineal body during childbirth predisposes to uterine prolapse. Peritoneal folds, such as the broad ligaments, uterovesical and rectovaginal ligaments, do not contribute much to the support of the uterus.

### STRUCTURE AND FUNCTIONS

The uterine wall consists of three layers: *perimetrium*, *myometrium*, and *endometrium*. The perimetrium is the peritoneal covering of the uterus. It is firmly attached to the underlying myometrium everywhere except over the lower part of the anterior surface adjacent to the isthmus and on the posterior surface of the uterus in the region of the supravaginal cervix. Here it is separated from the muscular wall by loose areolar tissue and it can be easily stripped off from the uterus. This looseness of the peritoneum helps in adequate mobilization of the urinary bladder during operations. The muscular wall—or myometrium—of the uterus is composed of smooth muscle supported by connective tissue. The endometrium is the mucosal layer of the uterus. It is continuous with the lining of the uterine tubes superolaterally and with that of the vagina inferiorly. It consists of a single layer of columnar cells resting on a thick lamina propria made up of connective tissue called the endometrial stroma. Many tubular endometrial glands extend through the entire thickness of the endometrium and may occasionally penetrate the myometrium for a short distance. From puberty to menopause, the endometrium undergoes extensive changes during the menstrual cycle in response to ovarian hormones and is partly sloughed off each month during menstruation.

## APPLIED ANATOMY

The cervix and the body of uterus may be examined by bimanual palpation. With the bladder empty, the vaginal portion of the cervix is palpated with two digits of the right hand while the other hand is pressed inferiorly and posteriorly in the pubic region of the anterior abdominal wall. The size and position of the uterus can be determined in this way. In most women, the uterus is anteverted and anteflexed (Fig. 22.2). A retroverted, retroflexed uterus can be palpated through the posterior vaginal fornix.

The cervix normally has a firm consistency similar to the tip of the nose, but in the pregnant uterus it is soft and vascular. Similarly, there is softening of the isthmus of the uterus in pregnancy (Hegar's sign). A speculum examination allows the cervix to be visualized in order for microbiological and cytological samples to be taken and cervical procedures to be undertaken (Fig. 22.4).

The tone of the levator ani muscles is of great importance in supporting the uterus. Loss of tone may predispose to uterine prolapse.

## Uterine Tubes

### STRUCTURE

The two *uterine (fallopian) tubes* lie on either side of the uterus in the medial three-quarters of the upper free border of the broad ligament. This part of the broad ligament is called *mesosalpinx*. Each tube is 10–12 cm long and, for descriptive purposes, can be divided into four parts (Fig. 22.1b).

Fig. 22.4: View of the cervix during speculum examination.

- (i) **Infundibulum:** The lateral end of tube is 3 mm wide when relaxed and is funnel-shaped. Its opening or *ostium* is surrounded by finger like processes called the *fimbriae*.
- (ii) **Ampulla:** Extending for more than half the length of the tube, this thin-walled section of the uterine tube has a wider lumen and is the commonest site in which fertilization takes place.
- (iii) **Isthmus:** This is the medial third of the uterine tube. It is the narrowest part, 0.1–0.5 mm in diameter with the thickest muscular layer in its wall. The round ligament lies immediately anterior to this part of the tube and can be mistaken for it during laparoscopic sterilization.
- (iv) **Uterine (intramural) part:** This part of the tube pierces the myometrium and its narrow lumen, measuring only 1–2 mm in diameter, opens into the uterine cavity at the *uterine ostium*.

The uterine tube is composed of three layers—the *serosa*, the *muscular layer*, and the *mucosa*. The tubal mucosa is composed of secretory and ciliated columnar cells. It is invaginated to form folds called major plicae, with secondary and tertiary folds.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The arterial supply to the uterine tube is provided by tubal branches of the uterine and ovarian arteries. Venous drainage is provided by corresponding tubal branches which drain into the uterine and ovarian veins. Lymphatic vessels follow those of the uterine fundus and ovaries to ascend with the ovarian vein into the para-aortic lymph nodes. The nerve supply of the uterine tubes is derived from the ovarian and uterine plexuses. Afferent fibers from the tubes are contained in the T11, T12, and L1 nerve roots.

### FUNCTIONS

Once released from the ovary at ovulation, the oocyte is 'picked up' at the fimbriated, lateral end of the uterine tube. The action of the ciliated epithelium and contraction of the smooth muscle in its wall facilitate the movement of the oocyte toward the uterine cavity. Along the way, sperm, travelling along the conduit provided by the uterine tubes, may reach the oocyte. If fertilization takes place, the uterine tube additionally provides nourishment for the fertilized ovum and transports it to the cavity of the uterus.

### APPLIED ANATOMY

Sexually transmitted pathogenic bacteria may ascend through the uterus to enter the uterine tubes causing *salpingitis*. Because the female genital tract is in direct communication with the peritoneum, the infection may spread to cause a general *peritonitis*. Conversely, salpingitis may result from infection that spreads from the peritoneal cavity. Salpingitis may result in the formation of

adhesions which slow down the passage of the zygote and may result in a tubal ectopic pregnancy.

*Pyosalpinx* is the collection of pus in the uterine tube. *Hydrosalpinx*, a collection of fluid within the fallopian tube, is the result of occlusion of the tube by adhesions at both ends. It may be asymptomatic.

Tubal ectopic pregnancies are the commonest form of ectopic pregnancy. If not diagnosed early, they may result in tubal rupture and hemorrhage into the abdominopelvic cavity, which may constitute a threat to the mother's life.

Over 90% of female sterilization is done by ligation of the uterine tubes. Oocytes released from the ovary are prevented from coming into contact with sperm and die within the uterine tubes.

## Vagina

The vagina is a musculomembranous tube that extends upward and posteriorly from the vulva to the uterine cervix. It is 7–9 cm long and has anterior and posterior walls, which are normally in apposition except at its superior end where the anterior wall is pierced by the cervix, which in the majority of women, projects inferoposteriorly. The posterior wall is about 1 cm longer than the anterior wall. The upper half of the vagina lies above the pelvic floor and lower half lies within the perineum. The area of the vaginal lumen that surrounds the cervix is divided into four regions or fornices—anterior, posterior, right lateral, and left lateral.

Anteriorly, the vagina is closely related to the bladder above and the urethra below. Posteriorly, its upper third is related to the pouch of Douglas and middle third, the ampulla of the rectum, and the lower third, the perineal body, which separates it from the anal canal. Lateral to the upper part of the vagina lie the ureters. The middle part of the vagina is related to laterally to the anterior fibers of the levator ani muscle as they run backward to reach the perineal body. Contraction of the fibers of levator ani muscle compresses the walls of the vagina together. The lower part of the vagina is related to the urogenital diaphragm and the bulb of the vestibule.

### SUPPORTS OF THE VAGINA

The principal supports of the upper part of the vagina are the transverse cervical, the pubocervical and uterosacral ligaments (Fig. 22.5). The lower part of the vagina is supported by the perineal body and the pubovaginal part of the levator ani muscle.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The *vaginal artery* is usually a branch of the uterine artery, although sometimes it arises from the internal iliac artery. The two vaginal arteries anastomose with each other and the cervical branch of the uterine artery. The vagina is additionally supplied by the internal pudendal artery and the vaginal branches of the

**Fig. 22.5:** Ligamentous supports of the uterus as seen from below (a) and laterally (b).

middle rectal artery. The vaginal veins form a plexus along the sides of the vagina and drain into the internal iliac veins. The lymphatic vessels from the upper third of the vagina drain into the external and internal iliac lymph nodes, the middle third to the internal iliac nodes, and those from the lower third to the superficial inguinal lymph nodes. The upper third of the vagina is supplied by autonomic nerves from the uterovaginal plexuses. The lower two-thirds have a somatic nerve supply from the pudendal nerve.

### STRUCTURE AND FUNCTIONS

The vaginal wall has three layers. The outermost is a thin layer of loose connective tissue with a rich plexus of blood vessels and occasional lymphoid follicles. Next, the muscular coat has outer longitudinal and inner circular layers of smooth muscle fibers. The mucous membrane is the innermost layer, consisting of stratified squamous, non-keratinized epithelium, it is devoid of glands. Due to the action of lactobacilli present in the vagina, vaginal transudates have an acidic pH of about 4.5 which protects the vagina from bacterial invasion. During infancy and after menopause, the vaginal acidity diminishes therefore bacterial

invasion may be more common. The epithelium gets keratinized when exposed to air, as occurs with significant degrees in uterine prolapse. The vagina not only is the female organ of copulation but also serves as the excretory duct for menstrual flow and forms part of the birth canal.

### APPLIED ANATOMY

During a *digital vaginal examination* (*per vaginal examination*), the uterine cervix is palpated superiorly, the ovaries and uterine tubes laterally, and the bladder, urethra, pubic symphysis anteriorly. The rectum may be palpated posteriorly (via the rectouterine pouch). The vagina may also be palpated by *digital rectal examination*. Here the index finger inserted into the anal canal facilitates the palpation (again via the rectouterine pouch) of the vagina and cervix and perineal body (Fig. 22.3).

A *cystocele* results from the bulging of the anterior vaginal wall due to slackening of support of the bladder. A *rectocele* results from the sagging of the ampulla of the rectum against the posterior vaginal wall.

Owing to the anatomical relationships of the vagina, any instrument directed posteriorly into the vagina may perforate the posterior wall and enter into the peritoneal cavity (via the rectouterine pouch). Peritonitis may subsequently ensue. Lacerations in the posterior fornix may also cause prolapse of the small intestine into the vagina.

*Uterine prolapse* is necessarily associated with some degree of sagging of the vaginal wall. A prolapsed uterus is graded based on level of descent: to the upper vagina (first degree), to the introitus (second degree), or external to the introitus (third degree or total, sometimes referred to as *procidencia*). Vaginal prolapse, the descent of the vagina, or vaginal cuff post hysterectomy, may be termed second or third degree.

### Female External Genitalia

The term *vulva* is the collective name for the female genitalia and includes the *mons pubis*, *labia majora*, and *minora*, *clitoris*, *vestibule*, the *greater vestibular glands*, the *orifice of vagina*, and *bulb of the vestibule* (Fig. 22.6).

The *mons pubis* is a rounded, hair-bearing elevation of skin, found anterior to the pubis. The pubic hair in the female has an abrupt horizontal superior margin, whereas in the male it extends upward to the umbilicus. The labia majora are prominent hair-bearing folds of skin extending posteriorly from the mons pubis to about 2.5 cm from the anus. Anteriorly they unite to form the *anterior labial commissure*. Posteriorly they are separated in the midline by the *posterior labial commissure*. Embryologically, the labia majora are homologous to the male scrotum.

The *labia minora* are two smaller, hairless folds of soft skin that lie between the labia majora. They consist of a core of spongy tissue with blood vessels and many sensory nerve endings. The labia minora enclose the vestibule and united posteriorly in the abrupt fold called the *fourchette*. Anteriorly they unite above the clitoris, forming an anterior prepuce or clitoral hood.

Fig. 22.6: Female external genitalia.

The *clitoris* is a small cylindrical erectile body rarely exceeding 2–3 cm in length. It is homologous to the male penis, but neither it is transversed by the urethra nor does it contain corpus spongiosum. The clitoris consists of a root and a body composed of two crura, two corpora cavernosa, and a glans (Fig. 22.7). The glans is less than 5 mm in diameter, is covered by squamous epithelium, and is partly hidden by the prepuce. It is richly supplied by nerves and is extremely sensitive.

The vestibule is the area bounded anteriorly by the clitoris, posteriorly by the fourchette, and on each side by the labia minora. It represents the urogenital sinus of embryo. It is perforated by openings of the urethra, vagina, ducts of the greater vestibular (Bartholin's) glands, and ducts of the paraurethral (Skene's) glands.

The vestibular bulbs lie beneath the mucus membrane of the vestibule on either side of the lower end of the vagina and the urethra (Fig. 22.7). Each is 3–4 cm long, 1–2 cm wide, and 0.5–1 cm thick. The vestibular bulbs consist of erectile tissue and are homologous to the bulb of the male penis. Unlike the penis,

Fig. 22.7: Structures underlying the female urogenital triangle.

however, they are separate from the clitoris and separated from one another by the vestibule. Their posterior ends are expanded and are in contact with the greater vestibular glands. They may be injured during childbirth or episiotomy, and may give rise to hematoma of the vulva or cause profuse hemorrhage.

The female urethra is 3–4 cm long. It extends from the neck of the bladder to the external urethral meatus, where it opens into the vestibule about 2.5 cm below the clitoris. The orifice is usually puckered and appears as a vertical slit with slightly raised margins. At the sides of the urethral opening are the small openings of the ducts of the paraurethral (Skene's) glands. These are a pair of small mucous glands lying on each side of the lower end of the urethra. They are homologous to the prostate in men. The ducts of these glands open usually in the vestibule on either side of the urethra but may open inside the posterior urethral wall just inside the urethral opening. The opening of each duct is only 0.5 mm in diameter.

The greater vestibular glands or Bartholin's glands are a pair of round or oval bodies, measuring about 0.5–1 cm in diameter. They lie partially overlapped by the vestibular bulb posterolateral to the vaginal orifice (Fig. 22.4). These glands are homologous to the male bulbourethral (Cowper's) glands. Slender ducts, about 2 cm in length, open from either gland into the vestibule in the groove between the hymen and the posterior part of the labium minus. Clear or whitish mucus is secreted by these tubuloalveolar glands in response to sexual stimulation. These glands have been demonstrated to have cells with endocrine function, which secrete serotonin, calcitonin, bombesin, ketacalcin, and human chorionic gonadotrophin. The glands are frequent sites of an abscess or cyst formation (Fig. 22.8).

The vaginal orifice is located in the posteroinferior part of the vestibule and varies considerably in shape and size. The hymenal remnant is a thin fold of mucous membrane surrounding the vaginal orifice.

### BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The vulva has a rich arterial blood supply arising from the branches of the external pudendal artery, a branch of the femoral artery, and branches of the internal pudendal artery.

Fig. 22.8: Bartholin's cyst.

Corresponding veins drain into the external and internal pudendal veins. The anterior parts of the vulva including the mons pubis are innervated by the ilioinguinal and genitofemoral nerves. The posterior parts of the labia and the perineal region are supplied by the labial branches of the perineal nerve, a branch from the pudendal nerve, and perineal branches of the femoral (posterior) cutaneous nerve of the thigh. The vulva has rich lymphatic network. Lymphatics from the vulva, perineal skin, and the lower part of vagina drain into the medial group of superficial inguinal lymph nodes, while lymphatics from the clitoris and deep structures drain into the deep group of inguinal and internal iliac lymph nodes.

### APPLIED ANATOMY

The presence of numerous glands and ducts opening onto the surface of the vulva renders this area prone to infection. The sebaceous glands of the labia majora, the greater vestibular glands, the urethra, and the paraurethral glands can all become infected.

In pregnancy, the vulval appearance may change to reveal a bluish discoloration as a result of venous congestion. This appears between the 8th and 12th weeks of gestation and increases as the pregnancy progresses.

Cystitis is much more common in females than in males owing to the short length of the female urethra which predisposes to ascending infection. Catheterization is also easier in females than in males because the female urethra is shorter, wider, and more dilatable. Moreover, the urethra is straight and only minor resistance is felt as the catheter passes through the urethral sphincter.

Due to the rich arterial supply to the vulva, hemorrhage from vulval injuries may be severe. During parturition, the most pain is usually felt when the fetal head passes through the vulva due to stretching of its parts. A pudendal nerve block can be used for anesthesia during child birth, where local anesthetic is injected around the pudendal nerve supplying this area.

An episiotomy is an incision made in the perineum to permit delivery of the fetus without perineal laceration.

# Normal Genital Flora

Frances E. Keane

## Introduction

Although the intrauterine environment is completely sterile, from the time of delivery the neonate is exposed to a multitude of organisms from sources such as the birth canal and the hands of carers. Thus, gradually the skin, oropharynx, gastrointestinal tract, and other mucosal surfaces become colonized by microbes. The vagina and cervix, as well as the urethra in both sexes, have an established microflora. Although this chapter will refer to the other sites, its focus will be the endogenous vaginal flora as evidence accumulates for its protective role against the development of bacterial vaginosis (BV), the main cause of abnormal discharge in women of childbearing age, and the acquisition of sexually transmitted infections, including HIV.<sup>1</sup>

## Female Genital Flora

### VAGINAL FLORA

There have been many studies of the endogenous flora of “normal women” however, these should be interpreted with some caution as the definition of “normal” varies between studies as do the methods employed to identify and quantify bacteria. Collectively, the available studies provide a useful overview regarding trends of species colonization; however, it is widely acknowledged that the full spectrum of organisms comprising the healthy vaginal flora has yet to be described.<sup>2</sup>

In healthy women of child-bearing age the vagina is an acid environment, although transient elevations in pH are created during events such as coitus, by the introduction of sperm, and menstruation. In 1894, Doderlein published his definitive study describing Gram-positive bacilli (rods), subsequently named *Lactobacillus* spp., as the dominant constituents of the vaginal flora of healthy women.<sup>3</sup> However, it was later realized that although lactobacilli dominate, the normal vagina contains a mixed flora including other facultative (replicating in the presence or absence of oxygen) and strictly anaerobic organisms. Quantitative studies have reported isolation of facultative lactobacilli in up to 96% of healthy volunteers.<sup>4,5</sup> Over time, opinion has varied

as to which species of lactobacilli predominate; early studies reported *L. acidophilus* and *L. fermentum* to be most commonly isolated.<sup>6,7</sup> However, subsequent use of DNA homology and other nucleic acid technologies have confirmed *L. crispatus* and *L. jensenii* to be the predominant species in the healthy vagina.<sup>8,9</sup> Other less commonly isolated Gram-positive bacilli include *Eubacterium* spp., *Bifidobacterium* spp., *Propionibacterium* spp., and *Clostridium* spp.<sup>10</sup>

The second commonest isolates from the normal vagina are Gram-positive cocci. These include facultative anaerobic organisms such as coagulase-negative staphylococci and streptococci, including group B beta-hemolytic streptococci and *Enterococcus* spp.<sup>11</sup> Anaerobic Gram-positive cocci have also been isolated in up to 80% of pre-menopausal women, the most common being *Peptostreptococcus asaccharolyticus* and *P. prevotti*.<sup>12</sup>

Gram-negative rods are also isolated from the healthy vagina in up to 40% of women; these include *Gardnerella vaginalis* and *Bacteroides* spp. *Fusobacterium* spp. and *Mobiluncus* spp. are much less frequently isolated from healthy women.<sup>12–15</sup> Interestingly, *G. vaginalis* was first described by Gardner and Dukes in 1955, as the sole and unique causative organism of “non-specific vaginitis,” subsequently renamed BV. However, BV is now recognized as a condition of mixed flora in which the organisms mentioned above are found in greater numbers than in women with healthy vaginal flora.<sup>15</sup> Other Gram-negative rods isolated infrequently from the healthy vagina include *Enterobacteriaceae* spp., *Escherichia coli*, and *Klebsiella* spp.<sup>4</sup>

Gram negative cocci, such as *Veillonella* species, are infrequently isolated from the healthy vagina.<sup>15</sup> Other organisms, such as *Mycoplasma hominis* and *Ureaplasma urealyticum*, both of which lack cell walls, are common constituents of the vaginal flora, yet both are isolated in smaller numbers from healthy women compared to those with BV.<sup>15,16</sup> *Candida albicans* is the most common yeast isolated from the healthy vagina.

In the clinical setting, microscopy of Gram-stained vaginal samples provides a cost-effective and relatively straightforward method of obtaining a “snapshot” of the vaginal flora. This provides an extremely useful near-patient diagnostic test to assist in the

diagnosis of women presenting with vaginal discharge, particularly those with BV. The Ison–Hay classification method<sup>17</sup> describes five different categories of vaginal flora and has compared well against more complicated scoring systems. The five categories are: grade 0, epithelial cells only with no bacteria present; grade 1, normal, *Lactobacillus* spp.-dominated flora; grade 2, intermediate flora with reduced numbers of lactobacilli and mixed flora; grade 3 (BV), mixed bacterial flora only; and grade 4, Gram-positive cocci alone. Illustrations of normal vaginal flora can be seen in Figures 23.1 to 23.3.

## Factors Influencing the Vaginal Flora

The vaginal flora is subject to many influences, including hormonal status, menses, contraceptive practices, and sexual activity.

**Fig. 23.1:** *Lactobacillus* morphotypes (Gram-positive [purple] rods) on a background of epithelial cells. Courtesy: Dr. Richard Bendall.

**Fig. 23.2:** Short *Lactobacillus* morphotypes. Courtesy: Dr. Richard Bendall.

**Fig. 23.3:** Mixed *Lactobacillus* morphotypes, including some long forms. Courtesy: Dr. Richard Bendall.

## Hormonal Status

The hormonal status of women varies under the influence of age, the transient shifts of the menstrual cycle, and the use of exogenous hormones in both contraceptives and hormone-replacement therapy.

## Age-Related Effects

For the first 3 or 4 weeks following delivery, the neonatal vagina is under the influence of maternal estrogen; the vaginal epithelium is anatomically and physiologically similar to that of the mother and facultative lactobacilli predominate.<sup>18</sup> Thereafter, maternal estrogen is gradually metabolized, the vaginal epithelium exfoliates, acid production is lost and the vaginal pH rises. Facultative lactobacilli are lost and are replaced by skin commensals such as coagulase-negative staphylococci and fecal organisms such as *E. coli*. With the onset of puberty, the vagina is subject to the influence of estrogen once more, the glycogen content is re-established, lactic acid is produced by glycogen metabolism and the healthy vagina is colonized by a *Lactobacillus*-dominated flora. At menopause, the vaginal appearance gradually reverts to that of pre-menarche in women not on estrogen replacement therapy. Facultative lactobacilli are isolated in less than 50% and *G. vaginalis* and genital mycoplasmas are also less frequently isolated.<sup>19</sup>

## Menstrual Cycle

An early quantitative, sequential study of vaginal flora over the menstrual cycle reported a sharp pre-menstrual decrease in concentrations of facultative microbes and a constant concentration of anaerobes throughout the cycle.<sup>12</sup> Other workers reported no overall decrease in the concentration of bacteria although anaerobic lactobacilli predominated during menses and facultative lactobacilli in the remaining three weeks.<sup>20</sup> The greatest species diversity occurred during menses. A subsequent,

larger study reported a slight decrease in the rate of recovery of *Lactobacillus* species during menses and a decrease in the prevalence of other species outside that time.<sup>21</sup>

Studies of sequential, Gram-stained, vaginal samples over the menstrual cycle reveal a variety of patterns of vaginal flora, that is, normal flora throughout, abnormal flora throughout, and either predominantly normal or abnormal flora that undergoes a transient shift.<sup>22–24</sup> In all studies, transient shifts toward an abnormal flora occurred around the time of menses. During menses the vaginal pH undergoes a temporary elevation but the true reasons for the shifting patterns of vaginal flora are poorly understood. The published data on the use of catamenial products suggest that there is no sustained difference in vaginal populations of facultative and anaerobic organisms between users of tampons and sanitary towels.<sup>25</sup>

### Pregnancy

There are conflicting data regarding the effect of pregnancy on the composition of vaginal flora. Some workers report that women with abnormal flora in early pregnancy have a tendency to revert to normal as pregnancy progresses,<sup>26</sup> but other studies, albeit of shorter duration, have produced conflicting results.<sup>27</sup> However, it remains undisputed that abnormal vaginal flora, particularly BV, is associated with an increased risk of pre-term labor and other adverse pregnancy outcomes.

### Hormonal and Other Types of Contraception

The combined oral contraceptive pill and consistent condom use appears to promote maintenance of the normal vaginal flora.<sup>28,29</sup> While some workers<sup>28</sup> have reported progesterone-only methods to be protective of the normal flora, others<sup>30</sup> suggest progesterone-only contraception produces a hypo-estrogenic state and a reduction in hydrogen peroxide ( $H_2O_2$ )-producing *Lactobacillus* spp., whose protective effects are described below. The use of the copper intrauterine contraceptive (IUCD) device is strongly associated with a change in the vaginal ecosystem to the detriment of facultative lactobacilli<sup>29</sup>; however, there is no available information on the effect of the progesterone-incorporated intrauterine system. The effects of the spermicide nonoxynol-9 are incompletely understood, although there is evidence to suggest that it may adversely affect the lactobacillus population.<sup>31,32</sup>

### Sexual Activity

The introduction of sperm causes a rise in vaginal pH, which can take up to 8 hours to return to normal.<sup>33</sup> A recent meta-analysis<sup>34</sup> reported an association between the loss of a *Lactobacillus*-dominated flora and sexual contact with new and multiple male partners. A similar association is found with exposure to female sexual partners.

Smoking<sup>35</sup> and genital hygiene practices, such as douching,<sup>36</sup> have also been associated with disruption of the normal vaginal flora.

## Protection Against Infection

Microbes can migrate to sterile areas, such as the uterus, ureters, and kidneys, causing disease; however, they face many challenges in order to do so. These include crossing either external keratinized epithelium or internal mucosal epithelial layers, the latter being covered by a thick mucus layer that is colonized by commensal microbes. Further obstacles include the innate immune system at epithelial surfaces, comprising cells with the capacity to express antimicrobial agents or mount a rapid antimicrobial response utilizing, for example, macrophages and natural killer cells. Additional defense mechanisms include antibody production and T cell activation at mucosal surfaces.<sup>37</sup>

As the dominant vaginal commensals, lactobacilli have a key protective role against colonization by both endogenous and exogenous pathogens, particularly with respect to the development of BV. *In vitro* studies have demonstrated the ability of lactobacilli to inhibit the growth of many species such as *G. vaginalis*, *Mobiluncus* spp., and *Bacteroides* spp.<sup>38</sup> Various methods of protection by endogenous lactobacilli have been proposed, among them the production of lactic acid as a by-product of *Lactobacillus* metabolism, thus contributing to the maintenance of a low vaginal pH. Furthermore, some *Lactobacillus* spp. produce  $H_2O_2$  which has demonstrated toxicity to *G. vaginalis* and *Prevotella bivia*, an effect enhanced by the addition of peroxidase and halide, both of which occur naturally in human secretions.<sup>39</sup>  $H_2O_2$ -producing *Lactobacillus* spp. are more prevalent in women of childbearing age than in pre-menarchal or post-menopausal women.<sup>40</sup> They have also demonstrated the ability to kill HIV *in vitro*.<sup>41</sup> The exact function of bacteriocins, also produced by  $H_2O_2$  lactobacilli, is unknown.

### CERVICAL FLORA

The cervix sits within the vagina and thus might be assumed to host identical resident microflora, but it does provide a different micro-environment to its vaginal counterpart. For example, while the vagina is of acid pH, that of the cervix is more neutral. In addition, while the surface of the vagina is covered purely by stratified squamous, nonkeratinizing, epithelium, as is the ectocervix, the endocervical canal is covered by columnar epithelium. The position of the squamo-columnar junction is under hormonal influence and may therefore be hidden inside the endocervical canal, or extend out over the ectocervix, typically in women who are pregnant or using the combined oral contraceptive pill. Comparison of the cervical and vaginal microflora suggests that although the patterns of aerobic and anaerobic bacteria isolated from both sites are similar, considerable differences are observed between paired samples from the same woman.<sup>42</sup>

### URETHRAL FLORA

Studies of healthy women have confirmed that the urethra, like the vagina, is colonized predominantly by *Lactobacillus* spp. and staphylococci.<sup>43</sup> However, in women prone to recurrent urinary

tract infections, Gram-negative enteric bacteria, mainly *E. coli* have been found to dominate the urethral flora.<sup>44</sup>

## Male Genital Flora

There have been fewer studies of the normal male genital flora. Bowie et al.<sup>45</sup> compared men with and without urethritis and reported that aerobic lactobacilli, *G. vaginalis*, alpha-hemolytic streptococci, and anaerobes, predominantly *Bacteroides* spp., were more likely to be isolated from men without, than from those with, urethritis. In a more recent, semi-quantitative study<sup>46</sup> of 30 uncircumcised men, samples obtained from the external urethral orifice, navicular fossa, and penile urethra revealed the flora to be dominated by Gram-positive aerobic bacteria, with the most common species identified being staphylococcus coagulase-negative spp., group viridans alpha-hemolytic streptococci, *Corynebacterium* spp., and *Enterococcus* spp. A variety of *Malassezia* and, to a lesser extent, *Candida* yeasts are also isolated as part of the resident male genital micro flora in both circumcised and uncircumcised men although colonization patterns may vary according to circumcision status.<sup>47,48</sup> In another study from the urethra of 50 sexually inexperienced adolescents: aerobes (66%), *Staph. epidermidis* (28%) and diphtheroids (20%) etc. were the predominant isolates with hardly any potential pathogens: ureaplasma in 4% and Gardnerella in 2% only.<sup>49</sup> Male circumcision has been shown to reduce carriage of uropathogenic organisms by young boys.<sup>50</sup>

## Conclusion

The genital ecosystem is an intricate and dynamic environment, subject to many potential influences. Although a plethora of studies have already been undertaken, the composition of genital flora has not yet been completely elucidated. This is an area of understanding that should improve over the coming years with the advent of new technologies for the detection of organisms. In addition however, we need to gain a greater understanding of how endogenous flora operate within the complex host immune system and other organisms achieve pathogenic status before we can best appreciate how to prevent genital infection.

## History and Physical Examination

Keith Radcliffe

### Introduction

As in all medical consultations, the combination of taking history from the patient and performing physical examination forms the cornerstone of the management of a person presenting because of concerns relating to sexually transmitted infections (STIs). In addition, the obtaining of appropriate samples for specialized microbiological investigations will often be done in the course of the physical examination. Even where a diagnosis of STI is unlikely, and no abnormalities are found on examination, the mere fact of having been carefully examined by a trained practitioner will often be very reassuring to an anxious patient.

Each consultation represents a unique event, and the manner in which it is conducted will be influenced by a variety of factors, including the cultural and religious background of the patient, and the prevailing legal, professional, ethical, and regulatory frameworks in operation. However, certain universal principles will always apply, very importantly those relating to privacy and confidentiality, and the right to have their dignity respected. The right to privacy is enshrined in Article 12 of the Universal Declaration of Human Rights: "No one shall be subjected to arbitrary interference with his privacy ..." <sup>1</sup> In all cultures sexual relations are held to be a private matter, and confidentiality in this field is therefore always of utmost importance. This has been recognized by the World Medical Association, which has stated that: "The physician shall respect a patient's right to confidentiality," and that a breach of confidentiality can only be justified when "... there is a real and imminent threat of harm to the patient or to others and this threat can be only removed by a breach of confidentiality." <sup>2</sup> Practical implications of this are that whenever possible, only the practitioner and the patient should be present during the consultation, and that steps be taken to prevent the consultation being overheard. Ideally it should be conducted in a private room which is adequately soundproofed, and the doors should be kept closed. All efforts should also be made to minimize interruptions. Sometimes another person may be present, for example, a trainee healthcare worker, an interpreter, or a family member. With regards to the presence of trainees, it

should be noted that the World Medical Association has stated that: "The patient has the right to refuse to participate in ... the teaching of medicine." <sup>3</sup> Therefore, the patient's permission for a trainee to be present during the interview should be obtained in advance without duress. The presence of family members, partners, or spouses during the consultation can also be problematic. The patient should be asked if they wish this person to be present, as their being there may be a barrier to obtaining a full and frank history, particularly in relation to sexual activity. If asked in the presence of the family member or partner, the patient may feel too embarrassed to refuse, so whenever possible they should be asked about their wishes with regard to this in private. Another complication that may arise is that a family member or partner may ask to act as interpreter. Again this may be a barrier to obtaining an accurate history, and every effort should be made to utilize an interpreter who is unknown to the patient.

It is important to realize that there is no single best way to conduct the history and examination. Each individual practitioner will inevitably develop their own habitual style over time. It is worth paying some attention to this, as developing a logical routine will improve the efficiency of the process, and lessen the possibility of omissions. This may be aided by the design and use of stylized pro formas for recording the essential elements of the history and examination, and this can be extended to include a note of the routine laboratory investigations requested, and the results of these when they are received. It is also important not to become a slave to routine. Although many consultations may follow a rigid pattern, the questions asked and the elements of the examination need to be tailored to the clinical situation, with particular regard to the presenting complaint, knowledge about exposure to sexual partners with specific conditions, and the local epidemiology of various infections. For example, a particular examination will naturally and quite rightly often be focused on the patient's anogenital area, but this may need to be extended, for example, to examination of mucocutaneous surfaces and palpation for lymphadenopathy in a person exposed to a contact with syphilis. The practitioner must also be flexible and be prepared to break off from his normal routine, in particular

when unusual responses are given to his questions. Finally, this chapter must be read in conjunction with other chapters in this book which address individual conditions in detail.

## Taking History

The questions should be asked in a systematic way, leaving the most sensitive ones (those relating to sexual activity) until later on. Traditionally the questions are asked in a face-to-face interview with a healthcare professional but in recent years innovative ways of obtaining the information have been developed. Asking the patient to complete a questionnaire prior to seeing the clinician would appear to be as good at eliciting the necessary information as the traditional interview.<sup>4</sup> Similarly, computer-assisted structured interviews, where patients enter the information directly into a computer in response to questions asked on screen or on audio, also appear to work well.<sup>5-7</sup> These approaches must be adapted to the local situation and may work better in some cultural contexts but less well in others. Issues of literacy and language skills are obviously important and systems must be in place to identify and assist those with problems in these areas.

If the history is obtained by questionnaire or computer then this is as a prelude to being seen by the clinician, and not a replacement for the consultation. The clinician will often need to expand upon the information obtained as required and might need to check and correct some of it.

The questions that need to be asked are for several distinct purposes:

- To establish the reason for the visit, in particular whether the patient has symptoms and if so what these are,
- To obtain details of recent sexual activity in order to decide what samples are required for microbiological (and possibly other) tests,
- To obtain information about risk behaviors for blood-borne viruses (HIV, hepatitis B and C) to inform choice of investigations, and to provide a basis for advice on reducing risk in the future, and
- To obtain general medical, gynecological, obstetric, menstrual, and contraceptive histories to inform decisions about investigation and management.

The following areas need to be addressed:

**Presenting complaint(s):** The reasons for the patient seeking a consultation about STI is best begun with a general, open question along the lines of: "What is the problem?" or "What can I do for you?" The practitioner should interject with additional questions to clarify statements made by the patient, and to seek further information as necessary. A degree of direct questioning will usually be necessary to inquire about symptoms suggestive of STI. This will require questions about specific symptoms localized to the genital tract, and also possibly related to systemic presentations of STIs, for example, weight loss, fever, skin rash, red eyes, night sweats, etc.

**Past medical history:** Firstly, relating to previous episodes of STI (obtain details about definite diagnoses, including when, where,

and how treated). Remember to enquire specifically about history of jaundice and vaccination against hepatitis B virus infection. Secondly, about significant past general medical problems, in particular, illnesses requiring hospitalization, surgery, or long-term treatment by a physician. Establish whether the patient is on any regular medications (and if so obtain details), whether they have received recent treatment with antimicrobials (say within the last month), and whether they have experienced allergic reactions to any prescribed medications.

**Family history:** Ascertain the patient's place of birth and upbringing. This is relevant in cases of suspected congenital syphilis, as this is more likely if the mother did not receive adequate antenatal care. It also has a bearing on the possibility of non-venereal treponematoses, hepatitis, and HIV infection, as these conditions are more likely if the person grew up or became sexually active in an area of high endemicity for these conditions.

**Gynecological history:** Menstrual history is important as this will have a bearing on possible pregnancy in women who have had unprotected sexual intercourse since their last menses. Also, symptoms related to the upper female genital tract, such as deep dyspareunia, intermenstrual bleeding, menorrhagia, and dysmenorrhoea, may suggest pelvic infection. The obstetric history is also important, both because a history of miscarriages may suggest prior infections (e.g., syphilis), and female patients may have been screened for various blood-borne sexually transmitted agents as part of past routine antenatal care, for example, hepatitis B and C virus infections, HIV, and syphilis. The woman's contraceptive history is important in excluding pregnancy, and she should also be asked about cervical cytology, especially where this is recommended as part of a national or local screening program

**Sexual history:** Always be aware of the need to establish the patient's sexual orientation beyond any possibility of confusion. It is always too easy to assume that the person is exclusively heterosexual. Enquire about recent sexual partners, extending back at least three months and possibly one year, as is deemed appropriate in the individual case. Obtain details concerning the date of the last coitus, the length of the sexual relationship, the type of sexual activity (particularly the type of penetrative intercourse that took place, specifically oral, anal, and vaginal penetration). Establish whether condoms have been used infallibly with each sexual partner. This requires that condoms should have been used for every act of penetrative intercourse, and for them to have been used properly, that is, for no penetration whatsoever to have occurred without a condom in place, and that the condom did not break or slip off during intercourse. Ask whether each partner is known to have complained of any symptoms that might suggest a diagnosis of a STI. Also enquire as to the country and region of upbringing of the partner, as this may influence the likely risk of individual STI, according to knowledge of their epidemiology in those areas. When obtaining a detailed sexual history for recent partners in this way, it is also worthwhile enquiring about the total number of sexual partners in the medium term, say in the last 12 months, as this helps to gauge the person's risk of having contracted an STI.

**HIV risk assessment:** Activities known to be associated with an increased risk of acquisition of HIV should be specifically enquired about. These include involvement in prostitution, male homosexuality or bisexuality, having injected drugs, sexual partners from areas of high endemicity, history of transfusion with blood or blood products, and sexual contact with intravenous drug users or (in the case of females) hemophiliac or bisexual male partners. Note that these factors will often indicate an increased risk of having been exposed to STIs other than HIV as well. It is important to remember that negative responses to these questions will not eliminate the need to consider testing for HIV infection, and this will be particularly true in areas where HIV transmission among the general heterosexual population is known to be frequent. Ask whether the patient has previously been tested for HIV, and if so, when and where this was carried out.

**Social history:** Ask about home and family circumstances, including nature of employment if any.

## Performing Physical Examination

It is not necessary to carry out a physical examination in all cases where a consultation is sought because of concerns about STI. As a general rule, the examination may safely be omitted in patients who report no symptoms. This is not only because examination of asymptomatic individuals is unlikely to be productive<sup>8–10</sup> but also advances in diagnostics mean that samples can be obtained non-invasively, obviating the need for a physical examination. Testing for chlamydia and gonorrhea can be done by using: urine samples for men<sup>11</sup> and women,<sup>12</sup> self-taken vaginal swabs for women,<sup>13,14</sup> and self-taken pharyngeal and rectal swabs for men who have sex with other men.<sup>15</sup>

In some cases it might be indicated to carry out a physical examination even in the absence of symptoms if the clinician believes that the patient is at high risk of STI. This likely to be because they are in a high-risk group, such as men who have sex with men or commercial sex workers, or because they give a history of sexual contact with an infected partner. It is not possible to be dogmatic on this point, since the clinician must exercise a judgment based upon their knowledge of the probability of disease in their own individual practice.

Consideration should always be given to having another member of staff present as a chaperone when carrying out an intimate physical examination on the patient. This applies whatever the genders of the practitioner and the patient. This meets several different needs: it reassures the patient, the chaperone is usually a nurse or other healthcare worker who is able to assist the practitioner in carrying out the examination, it provides a witness as protection against allegations of indecency or impropriety. The desirability of always having a chaperone present may have to be balanced against the resource implications, in that a member of staff may not always be available to act in this role.

The physical examination of both male and female patients is best carried out with the patient in the supine position. Attention should be paid to the position of both the patient and practitioner,

for example, in ensuring that the couch the patient lies on is at the optimal height for the procedure to be carried out. Bright lighting is required, and one source of this should be sufficiently flexible to allow illumination to be directed at the area under examination. It should go without saying that the examination room should be private and adequately sound-proofed; cubicles partitioned off by curtains are unsuitable, as any necessary conversation conducted during the examination can easily be overheard by third parties. Ensure that all necessary equipment and materials are to hand and laid out in a systematic way such that the examination can proceed with smooth efficiency from start to finish. It is desirable that the practitioner wear surgical gloves when carrying out the examination of the anogenital area. Such attention to hygiene is reassuring to the patient, and, also has the benefit of protecting the practitioner from possible infection, for example, from the infectious lesions of early syphilis. It is also important to ensure adequate exposure when examining the patient's anogenital area. If male patients do not remove all clothing from the lower half of the body, then trousers and underwear should be lowered to the knees or below. Women will need to be exposed from the waist down, as will men if proctoscopy is to be performed. As the examination proceeds talk to the patient, in straightforward language that they can understand, about what you are going to do. When appearances and findings are normal, provide continuous verbal reassurance to the patient that this is the case.

## GENERAL EXAMINATION

The need to extend the physical examination beyond the anogenital area should be guided by: symptoms complained of by the patient in the history, knowledge of the diagnosis in the patient's sexual partners, the patient's sexual history, and local epidemiology of specific conditions. Examples of STI which may have systemic presentations distant to the anogenital area are: HIV infection, secondary or tertiary syphilis, disseminated gonococcal infection, acute hepatitis B virus infection, and secondary lymphogranuloma venereum. Always remember that measuring the patient's vital signs, especially pulse rate and temperature, may also be very useful in such situations. At the end of the physical examination, consideration should be given to performing urinalysis for glycosuria. This is not indicated in asymptomatic patients but should be performed in cases of vulvitis or balanitis, as genital infection with candidiasis is a not infrequent mode of presentation of diabetes mellitus.

## Examination of Male Patient

### GENITAL EXAMINATION

Careful inspection of the genital and perigenital areas should be carried out and any cutaneous lesions noted carefully. Both inguinal areas should be palpated for lymphadenopathy. If enlarged lymph nodes are palpated, then attention should be paid to their number, size, and tenderness. Remember that not all swellings in the groin will be infective in origin (e.g., inguinal hernia, lymphatic

spread from carcinoma, and lymphoma) and that not all infective causes of inguinal lymphadenopathy will be due to STIs (e.g., plague, tularemia, and tuberculosis). Next, all surfaces of the penis should be carefully inspected. In an uncircumcised male the prepuce should be fully retracted to allow the subpreputial area, the coronal sulcus, and the glans penis to be visualized. Pay careful attention to the external urinary meatus for genital abnormalities, such as hypospadias, epispadias, and urethral duplication. Note the presence of any urethral discharge and if present, its volume and character (mucoid, mucopurulent, or frankly purulent). If no discharge is seen then “milk” the urethra by moving the fingers of one hand along the length of the underside of the penis while steadying the shaft of the penis in the other hand. This will express any secretions present in the urethra and render them visible at the meatus. If urethral samples are to be sent for microbiological investigations, then these should be obtained at this stage. Palpate the penis for indurations due to fibrous plaques of Peyronie disease or the presence of foreign bodies, strictures, periurethral abscesses, or urethral tumors. Next, examine the scrotum. Firstly, inspect the skin of the scrotum, noting, for example, prominent sebaceous glands which are often a source of anxiety to patients which can be addressed through strong reassurance. There may also be lymphedema, for instance in late lymphogranuloma venereum. Next, palpate the contents of the scrotum, paying particular attention to both testes and epididymis (which are located posterior to the testes). Bimanually examine both of these structures on each side. Note the presence of any mass. There are various causes for such a finding including, malignancy (the mass tends to be smooth or nodular, and painless), a gumma of the testis in tertiary syphilis, tuberculous involvement of the epididymis or testis<sup>16</sup> (hard and non-tender). Use a small torch to determine whether any mass present transilluminates. If it does then this suggests a benign cystic structure, such as a hydrocele or spermatocele. The absence of a testis suggests cryptorchidism or an abnormally retractile testis in an adult. Sometimes a testis is unusually small; if it is soft in appearance then this may indicate atrophy which could be congenital or the result of previous infection (especially mumps) or surgery (e.g., for herniorrhaphy, undescended testis, or torsion of the testis). Bilateral atrophic testes may indicate Klinefelter syndrome, which affects 0.2% of men leading to infertility and is a result of the presence of abnormal sex chromosomes (XXY). A unilateral painful swelling may be due to torsion of the testis and this must always be considered in the young adult as it represents a surgical emergency in which unnecessary delay may lead to serious adverse consequences. Or it may be a result of epididymo-orchitis, in which case there may also be an accompanying hydrocele. Epididymo-orchitis may be due to: an STI (especially chlamydia infection or gonorrhea), as a complication of a urinary tract infection, due to a viral infection (especially mumps),<sup>17</sup> or as a side-effect of medication (e.g., amiodarone). Rarely, a unilateral painful swelling results from a twisted appendix testis. Palpate the neck of the scrotum on each side between the finger and thumb; it should be possible to palpate the spermatic cord. Swellings in this area are usually due to hernias, hydroceles, or varicoceles. Varicoceles are due to enlarged

veins giving a “bag of worms” sensation on palpation, and usually disappear when the patient is recumbent.

## EXAMINATION OF ANORECTUM

Inspection of the perianal area should be carried out in male patients if they have symptoms. Perianal warts may be present in men<sup>18</sup> (and women) who are exclusively heterosexual. The examination is best done after examination of the genital area has been concluded. Ask the patient to roll into the left lateral position and to draw both knees up towards their body, but keeping their legs together and in contact with the couch. Separate the buttocks using both hands to allow inspection of the perineum and perianal areas. Make careful note of any lesion seen. These may indicate the presence of STI (e.g., condylomata acuminata due to infection with human papillomavirus, condylomata lata in secondary syphilis, or ulceration due to herpes simplex virus infection), or due to other pathologies (e.g., hemorrhoids, anal fissure, or fistula). Digital rectal examination should now be performed if indicated by symptoms suggestive of prostatic disease, that is, symptoms of outflow obstruction (nocturia, urinary frequency, and terminal dribbling of urine on micturition), or of prostatitis (i.e., perineal pain or discomfort). The gloved and lubricated index finger should be used to palpate the prostate anteriorly. A normal prostate has a diameter of approximately 4 cm, a rubbery consistency, and both lobes and the dividing median sulcus are palpable. An enlarged prostate may result from benign prostatic hypertrophy, malignancy, calculi, or chronic prostatitis. Tenderness of the prostate gland suggests prostatitis; this may be exquisite in acute prostatitis, due, for example, to gonorrhea. It should also be possible to feel the seminal vesicles, which are lateral to the prostate and extend superiorly. These may be abnormally enlarged in certain rare conditions, for example, tuberculous involvement. A rectal mass, likely to be malignant, may also be palpated with the finger. Proctoscopy with a well-lubricated instrument should be carried out if there are symptoms suggestive of proctitis (i.e., rectal discharge, tenesmus, or pain on defecation). The rectal mucosa should be examined visually through the instrument for the presence of erythema, discharge, and condylomata acuminata. If rectal samples are to be sent for microbiological investigation they should be obtained at this stage. Remember that digital and proctoscopic rectal examinations may not be possible in the presence of painful perianal lesions, such as thrombosed external hemorrhoids or herpetic ulceration.

## Examination of Female Patient

### EXTERNAL GENITAL EXAMINATION

This is best carried out with the patient in the dorsal lithotomy position. Careful inspection of the vulval and perivulval areas should be done. This will necessitate separating the labia majora using both hands, to allow visualization of the labia minora and the urethral meatus. Make careful note of any abnormal findings,

for example, enlargement of Bartholin's gland, condylomata acuminata, urethral discharge (pressure under the urethra with one finger may cause discharge to appear from the meatus), urethral caruncle, paraurethral abscess, vaginal prolapse, or lymphedema. Also separate the buttocks with both hands to allow examination of the perianal area and perineum. Later it may be necessary to examine the patient in the left lateral position to visualize the natal cleft.

### INTERNAL GENITAL EXAMINATION

A bi-valved, self-retaining speculum is preferred (Fig. 24.1). The examination can be rendered less uncomfortable for the patient if a metal speculum is pre-warmed by immersing it in warm water immediately prior to the examination. The labia majora should be separated with the fingers of one hand, and the speculum, in its closed position, slowly and gently inserted into the vagina to its full extent using the other hand. Once fully inserted the blades of the speculum should be gently opened, and in most cases the cervix will be visualized when this is done. If the cervix does not appear, then it may do so if the woman is asked to raise her buttocks off the couch temporarily. If this maneuver fails, then withdraw the speculum and perform a digital examination of the vagina with the lubricated and gloved index finger to locate the exact position of the cervix. Then re-insert the speculum in this direction. It may occasionally be necessary to use an extra-long speculum if the cervix cannot be reached with one of normal size. The cervix and vagina should be carefully inspected for normal features of note (e.g., retention cysts or Nabothian follicles on the cervix) and abnormalities, (e.g., condylomata, the 'strawberry cervix' of trichomoniasis, cervical mass, or ulceration). The consistency, color, and amount of any visible vaginal discharge should be noted. If required, vaginal and cervical samples for laboratory investigation should be obtained at this stage. Similarly, samples can be obtained from the endocervical canal after wiping the cervix with a cotton wool swab or ball to remove adherent vaginal secretions. The speculum should then

**Fig. 24.1:** A bi-valved, self-retaining speculum for internal genital examination in a female patient.

be removed with the blades in a nearly closed position. Be careful not to allow the blades to snap together, pinching the vaginal wall between them, as the instrument is removed. Any urethral samples for microbiological tests should be obtained at this stage. Consideration should be given to performing a bimanual pelvic examination. This is unnecessary if the woman complains of no upper genital tract symptoms. If it is indicated, then the lubricated index and middle fingers of a gloved hand should be inserted into the vagina, whilst the flat of the other hand should be placed on the woman's lower abdomen. Gently but firmly try to approximate the fingers of the two hands in order to palpate the pelvic structures between them; firstly in the midline to palpate the uterus, and then to either side to palpate the ovaries and adnexae (Fallopian tubes and associated ligaments). Do not exert such pressure as to cause the woman any pain. Take note of any abnormal enlargement of the pelvic organs, masses, unusual tenderness, or cervical excitation (i.e., unusual tenderness on gently moving the cervix with the index finger of the examining hand).

### EXAMINATION OF ANOURECTUM

Please refer to the section on the anorectal examination in male patients. Much the same considerations apply in females. A digital rectal examination is rarely indicated in a female patient attending for an STI screen, although it should be carried out if there are symptoms of gastrointestinal blood loss or altered bowel habit. Rectal samples to be tested for gonorrhea and/or chlamydia should be obtained in women who have practiced recent unprotected anal intercourse, and in those who are contacts of known gonorrhea, even if they have not practiced anal intercourse with that partner. These samples can be obtained by proctoscopy, or alternatively by blindly inserting a moistened cotton wool tipped swab through the anus.

### EXAMINATION OF MOUTH AND OROPHARYNX

This is not required routinely but should be done if the person complains of symptoms relating to the area, or if it is clinically indicated for another reason, for example, if the history suggests the possibility of syphilis or HIV infection.

A good light source is essential, and it must be possible to direct this into all parts of the oral cavity (a pen torch is very useful for this purpose). Carefully inspect in turn: the lips, gums, roof, and floor of the mouth, both surfaces, and the sides of the tongue. Look for leukoplakia, ulceration, nodules, and candidiasis.

To examine the oropharynx, ask the patient to open their mouth and to say "eh" or "ah," or to yawn, while holding the tongue down with a tongue blade. This is also the time to take a pharyngeal sample for microbiological testing if indicated (e.g., for gonorrhea in an individual giving a history of receptive fellatio), by quickly sweeping a swab around the oropharynx and tonsillar areas.

## Conclusion

Once the examination has been completed and all necessary samples obtained, the patient should be allowed to dress in privacy. Before they leave the clinic the examining physician should speak to them to discuss the findings, the possible diagnoses and their management, and to arrange follow-up.

In conclusion, the history taking, physical examination, and obtaining of specimens for laboratory investigations are the essential elements in making the diagnosis in a patient with possible STI. It is therefore important that the practitioner establish an efficient routine for carrying them out. On this will also rest the ability to form a satisfactory doctor-patient relationship without which management will fall short of optimal. This is even more true in this field of medicine than others, due to the feelings of shame and embarrassment that many patients will bring to such a consultation, which it is the duty of the physician to dispel through the application of his specialist knowledge, skills, and experience.

# Genital Mucosal Immunity Against Sexually Transmitted Infections

Satish K. Gupta • Manoj Modi • Nutan  
• Nachiket Shembekar • Shweta Malik  
• Suraj K. • Sanchita Chakravarty

## Introduction

The mucosal immune system is an integral part of the whole-body immune system and serves as first line of defense against pathogens transmitted via the respiratory, gastrointestinal, and genital routes. The investigations pertaining to mucosal immunity were hampered in the past by difficulty in isolating and characterizing mucosal associated lymphoid cells and measurement of secretory antibodies from various mucosal-associated tissues at the local site. Better understanding of the genital mucosal immune system is of paramount importance, as occurrence of sexually transmitted infections (STIs) is unabated. It has become even more critical to delineate the immune mechanisms occurring at the mucosal surface of the genital tract in light of the fact that 80–90% of persons infected with human immunodeficiency virus (HIV) acquire the infection through the sexual route.

Protection against STIs is derived either by innate or adaptive immune responses. The adaptive immune response is elicited against particular pathogens by the production of antibodies and/or cell-mediated immune response. Unlike the innate immune response, the adaptive immune response usually confers life-long protection to re-infection by the same pathogen. The adaptive immune system consists of two compartments, the systemic and the mucosal compartment, that are functionally independent.<sup>1</sup> The systemic compartment is represented by the bone marrow, spleen, and lymph nodes whereas the lymphoid tissues in the mucosa and the external secretory glands comprise the mucosal immune system. The mucosal immune system can be divided into discrete inductive (nasal associated lymphoid tissues [NALT], gut associated lymphoid tissues [GALT], and rectal associated lymphoid tissues [RALT]) and effector sites. The Peyer patches (PP), appendix, and smaller lymphoid aggregates called solitary lymph nodes appear to be the major inductive sites in GALT.

The commitment of B cells to form immunoglobulin-A (IgA), the major isotype of the mucosal immune system, is thought to occur in these inductive sites before enteric exposure to an antigen. The noninflammatory nature of IgA is probably of considerable importance for the maintenance of the structural

and functional integrity of mucosal tissues.<sup>2</sup> On encountering the antigen, B cells undergo expansion and differentiate into IgA plasma cells and memory cells. Following the migration of B cells to mucosal effector tissues, such as the lamina propria, and the epithelium of the intestine, upper respiratory, and genitourinary tracts, B cells develop into IgA plasma cells. The differentiation of B cells is facilitated by the presence of antigen specific T-helper (Th) cells as well as cytotoxic CD8+ T lymphocytes along with cytokines. Both CD8+ and Th cells also migrate along with the B cells from the inductive sites to the mucosal effector sites, the route constituting the common mucosal immune system.<sup>3</sup> The epithelial cells that cover the vast surface area of mucosal membranes integrally participate in mucosal immunity not only as mechanical barriers but also as active producers of innate immune factors (e.g., lysozyme, lactoferrin, peroxidase, defensins, complement components, and numerous cytokines). These cells are also involved in the transport of antibodies and act as antigen-processing and presenting cells.<sup>4</sup>

The immune system in the genital tract represents a component of the common mucosal immune system. However, the immune system of the genital tract is the least understood part of the mucosal immune system with respect to the origin of its immune cells, the role of cytotoxic T lymphocyte (CTL) responses, induction of antibody responses and the contribution of serum derived versus mucosally produced antibodies.<sup>3</sup>

## Female Genital Mucosal Immune System

The mucosal lining of the lower reproductive tract (vagina, ectocervix) is composed of multilayered stratified squamous epithelium whereas the upper reproductive tract (endocervix, endometrium) is composed of a single layer of columnar epithelium. The transformation zone between ectocervix and endocervix where the squamous epithelium abruptly changes to the single layer of columnar epithelium is more vulnerable to infection. Increased numbers of activated lymphocytes and lymphoid aggregates are present in the transformation zone in the presence of various pathogens.<sup>5</sup> Sexually transmitted viruses have to cross the female

genital tract epithelium to manifest infection in the host. Herpes simplex virus type 2 (HSV-2) directly infects genital epithelium and undergoes replication in it.<sup>6</sup> Sex steroid hormones modulate HSV-2 transmission and estradiol provides a protective effect.<sup>6</sup> The interaction of HIV with the genital epithelium is still not completely understood.<sup>7,8</sup> There are contradictory reports with respect to the infection of genital epithelium per se with HIV which may involve alternate cellular receptors such as GalCer, DC-SIGN, mannose receptors, heparin sulfate, and Syndecan.<sup>7-12</sup> Stages of the menstrual cycle and oral contraceptives have been shown to influence susceptibility to candidiasis, gonorrhea, HSV-2, HIV-1, and chlamydia in women.<sup>13,14</sup>

The mechanism of antigen uptake and processing in the female reproductive tract is analogous to a primary immune response in the GALT (Fig. 25.1). Antigens reaching the sub-mucosa of the vagina are taken up by antigen presenting cells (APCs), which then

migrate to the draining lymph nodes. In the female genital tract, Langerhans cells and mononuclear phagocytes present in the vagina are capable of acting as APCs. In mice, antigen absorption in the vagina occurs via Langerhans cells which are MHC class II+.<sup>15</sup> Once in the lymph nodes, the APCs stimulate B and T lymphocytes, including memory sub-populations, which enter the blood stream via the efferent lymph and the thoracic duct. These sensitized B and T lymphocytes migrate to the genital tract and on exposure to the antigen, participate in a secondary immune response.<sup>3</sup> Pathogens adapted to infect mucosa express virulence factors that allow them to adhere, colonize, or invade the epithelium. Secretory IgA (sIgA) prevents adsorption of these viruses, bacteria, and toxins by blocking their adhesion while they are on the external side of the epithelial barrier. By preventing cellular attachment of the antigen, IgA enables it to be flushed away in the stream of secreted fluids and mucous washing over the epithelia.

**Fig. 25.1:** Mucosal adaptive immune system of the female genital tract. Presence of a thick mucus layer in the female genital tract presents the first line of defense against pathogens. Antigen presenting cells (APCs) such as Langerhans cells and macrophages capture antigen and present the antigen to the immune cells in the draining lymph nodes. Activated B and T cells migrate to genital tract where exposure to antigen may lead to secondary immune response as well as generation of memory cells. Activated T cells are responsible for cell-mediated immunity, whereas activated B cells secrete antibodies leading to neutralization/opsonization of pathogens.

The types of immunoglobulins secreted in the female genital tract have been studied in secretions from the fallopian tube, uterus, peritoneal cavity, and in the cervical mucus or vaginal fluid. The hallmark of the mucosal immune system is the production of sIgA.<sup>3</sup> The presence of sIgA has been detected in the secretions of the female genital tract. Using sub-class specific monoclonal antibodies, equal proportions of IgA1 and IgA2 have been detected. Furthermore, in female genital tract secretions, IgA is represented by sIgA, polymeric IgA (pIgA), and monomeric IgA (mIgA), with a slight excess of IgA2.<sup>16</sup> Apart from IgA, cervical mucus secretions also show the presence of IgG (from the systemic circulation) in higher concentrations than IgA. The mechanisms involved in the appearance of IgG in cervico-vaginal secretions have not been explicitly elucidated. A 90% reduction in IgA and 50% reduction in IgG concentrations were observed in the mucus of hysterectomized women, providing indirect evidence that IgA is locally produced in the upper reproductive tract.<sup>17</sup> Human cervical mucus from normal women, sampled throughout the menstrual cycle contained albumin: IgG ratios that approximate those in the serum, suggesting that IgG is derived from the blood circulation.<sup>18</sup> Patients with abnormal cytology had higher concentrations of IgG and even more of IgA in the cervical mucus.<sup>19</sup> The cellular origin of Ig isotypes in the reproductive tract secretions have shown that the lamina propria of the endo- and ecto-cervix contains the highest numbers of Ig-producing plasma cells, with significant numbers being present in the fallopian tubes and vagina. Analyses by Flow Cytometry revealed that the reproductive tract tissues contain 6–20% of leukocytes, with the Fallopian tubes and uterus having a higher proportion of leukocytes than the cervix and vagina.<sup>20</sup> Among the leukocytes, T lymphocytes are a major constituent (30–60%). B cells and macrophages are also detected, but only in small numbers.<sup>20</sup> The uterine endometrium of post-menopausal women had fewer leukocytes than the uterine endometrium of pre-menopausal women. In addition, a hormone dependent change in the immune cell population has been observed in the reproductive tract. Sex hormones have a stimulatory effect on the immune function of females which becomes evident after menarche and diminishes after menopause.<sup>21,22</sup> In the human uterus, for example, immunocompetent cells exhibit a cyclic distribution during the menstrual cycle, representing 10–15% of the stroma during follicular phase and 20–25% in the late secretory phase. Immunophenotypic analysis of leukocytes in uterine endometria in hysterectomy specimens has shown the presence of lymphoid aggregates composed of a B lymphocyte core surrounded by numerous T lymphocytes and an outer layer of macrophages. The aggregates are present during the menstrual cycle in pre-menopausal women and are absent in post-menopausal women.<sup>22</sup> Increased numbers of plasma cells (especially IgA plasma cells) in the submucosa of the endocervix of women with a variety of STIs have also been detected.<sup>23</sup>

Innate immunity in the female reproductive tract utilizes a spectrum of molecules to confer protection against potential pathogens. Among the epithelial cell secretions, soluble factors

with known bactericidal effects are defensins, secretory leukocyte protease inhibitor, lysozyme, lactoferrin, and zinc, as well as other antimicrobial peptides.<sup>24</sup> Natural killer (NK) cells present in the female reproductive tract enhance innate immunity and play an important role in killing hazardous pathogens and tumor cells. The number of NK cells as a percentage of leukocytes in different regions of the female reproductive tract varies between 10% and 30% in non-pregnant women.<sup>20</sup> The differential expression of surface receptors by decidual NK cells may have a role in determining reproductive success through modulation of the maternal immune system at the time of implantation and placentation.<sup>25</sup> Decidual NK cells produce cytokines spontaneously and hence are able to amplify an inflammatory response and promote macrophage activation, endometrial angiogenesis, and generation of cytotoxic T cells.<sup>26,27</sup> Resting uterine NK cells express several toll-like receptors (TLRs), in particular TLR2, TLR3, and TLR4. It has been reported that activation of NK cells via TLR2 leads to release of  $\alpha$ -defensins that can be directly harmful to microorganisms.<sup>28</sup> NK cells have been established as an important effector of innate immunity for a variety of viral infections. In HIV-1 infection in humans, alterations of NK cell function, frequency, and expression of various NK receptors have been reported to be associated with differential dynamics of disease progression.<sup>29</sup> A depressed level of NK activity is one of the various immunological abnormalities observed during HIV infection.

Commensals which normally colonize the mucosa play a significant role in vaginal defense; these include *Lactobacillus* spp., *Staphylococci*, *Enterococcus* spp., *Gardnerella vaginalis*, *Ureaplasma urealyticum*, and *E. coli*. The lactobacilli metabolize glycogen released by vaginal epithelial cells to lactic acid resulting in a low vaginal pH (3.5–5.0) and thus create an acidic environment. Some species of lactobacilli also produce hydrogen peroxide, which is antimicrobial at a concentration of 0.75–5.0  $\mu$ g/ml. These levels of hydrogen peroxide are achievable in the vagina.<sup>30</sup> Keeping this in view, “probiotics” have also been proposed to combat STIs.

## Male Genital Mucosal Immune System

The male lower urogenital tract is exposed to sexually transmitted pathogens and is therefore a strategic site of immune defense. Immunologically, the penile foreskin is characterized by the presence of few T lymphocytes and macrophages. Numerous Langerhans cells, however, are found within the epithelium. The most abundant immune cells of the penile urethra are macrophages. In young adults, virgin male mice, these were found primarily underlying the urethral epithelium, but in older, mated mice, they were usually intraepithelial in location, and were more abundant. Langerhans cells could not be specifically identified in the urethral mucosa. T lymphocytes were found underlying and occasionally within the epithelium of the urethral mucosa, with CD4+ cells more abundant than CD8+ cells. The presence of ovalbumin specific IgA was observed in the urethral mucosa of rats when primed intraperitoneally with ovalbumin followed by intraduodenal plus intraurethral boosting.<sup>31</sup> Murine penile

urethral epithelium expresses secretory components, but few IgA producing plasma cells have been documented.<sup>32</sup> In primates, immunization targeting genital, urinary, and rectal associated lymphoid tissues produced specific IgA antibody titers in urethral secretions and seminal fluid.<sup>33</sup> In the male genital tract secretions, IgG, IgA, and IgM have been detected. In contrast to saliva, milk, and intestinal fluid, in which sIgA is by far the dominant isotype, seminal plasma contains IgG as the dominant isotype and IgM is present at low levels. IgA is represented by sIgA, pIgA, and mIgA, and all three molecular forms of IgA are present in comparable quantities. The levels of these antibodies show variation due to differences in collection procedures, methods, and standards used in immunoglobulin measurements, and the presence of proteolytic enzymes that are essential in semen liquefaction but also degrade immunoglobulins.<sup>34</sup> Parallel measurement of plasma-derived proteins and immunoglobulins in split ejaculates showed that IgG is derived from circulation, while sIgA is of local origin.<sup>35</sup> Detailed analyses of various types of antibodies and their sub-types suggest that humoral immunity in male genital tract is contributed to by both systemic as well as mucosal immune responses.<sup>36</sup> The presence of all the components required to mount a secretory mucosal immune response have been detected in the human penile urethra. IgA and IgM producing plasma cells have been detected along the length of the urethra. Antigen presenting cells have also been detected in the human penile urethra, suggesting that immunity may be induced in this region.<sup>35–37</sup> Recirculating lymphocytes from the thoracic duct entered the male genital organs with a similar distribution to the pattern of lymphoid blasts. There is probably an exchange between these immigrating lymphocytes and the different subsets, which are localized in the epithelium (T suppressor) and interstitial tissue (T helper) in male genital organs. The lymphoid cells in the male genital tract might play an important role in the immune function of seminal fluid and in sexually transmissible diseases. The presence in human seminal plasma of sIgA-associated antibodies to *S. mutans* and the influenza virus, as well as Salmonella-specific antibodies induced by oral immunization, suggests that the male genital tract is also a component of the common mucosal immune system.<sup>38</sup>

### Characteristic Features of the Genital Tract Immune System

The reproductive tracts (male and female) represent components of the common mucosal immune system with unique features which are distinct from other mucosal tissues. The majority of lymphocytes observed around the urethra are positive for the integrin beta 7 alpha M290, which is selectively expressed by mucosal lymphocytes, providing indirect evidence that the urethra is part of the common mucosal system.<sup>37</sup> On the other hand, both male and female genital tracts lack organized lymphoepithelial structures resembling intestinal PPs where mucosal immune responses are induced and transported to remote effector sites.<sup>39</sup> In contrast to GALT, within the uterine epithelium a hormone dependent lymphoid aggregation consisting of B cells, CD8+ T cells, and macrophages has been seen.<sup>3</sup> The

uterine mucosa is transformed from endometrium to decidua during pregnancy and this process is characterized by the presence of a large number of uterine NK cells that are distinct from most NK cells in the peripheral circulation.<sup>40</sup> Immunochemical analysis of female and male genital tract secretions have demonstrated that these fluids display several features that are distinct from other secretions. IgG predominates as compared to IgA both in male and female genital tract secretions, whereas IgA predominates in the gut-associated immune response.

### Characterization of Genital Tract Immune Response to Commonly Occurring STIs

Innate immunity plays a crucial role in combating STIs. The components of cellular immunity of the innate immune response include activated macrophages and NK cells. The components of humoral immunity of the innate immune response include members of the complement cascade and soluble pattern-recognition receptors, such as collectins, ficolins, and pentraxins.<sup>41</sup> These molecules represent functional ancestors of antibodies and play a key role as effectors and modulators of innate resistance in animals and humans as shown in Fig.25.2. Pentraxins are a superfamily of conserved proteins characterized by cyclic multimeric structure and presence of conserved “pentraxin domain” and “pentraxin signature.” The C-reactive protein and serum amyloid P components constitute the short pentraxin arm of the superfamily and play an important role in providing innate resistance to microbes.<sup>42</sup> PTX3 is a prototype long pentraxin produced by cells involved in innate immunity and by other peripheral tissues. PTX3 binds specific pathogens, such as fungi, bacteria, and viruses, promoting phagocytosis and consequent clearance of the pathogen.<sup>43,44</sup> Surfactant protein A, a member of collectin family of proteins is expressed in the vagina, has the ability to facilitate phagocytosis of microorganisms, stimulate chemotaxis, increase the oxidative burst by phagocytes, and modulate proinflammatory cytokine production by immune cells.<sup>45</sup>

Innate immunity depends on detection of the constituents of pathogens by the TLR family. To date, 10 TLRs (TLR1–10) in humans and 12 TLRs (TLR1–9 and TLR11–13) in mice have been found. Although present in mice, the human TLR11 gene appears to contain a stop codon that would prevent its expression. TLRs recognize pathogens through evolutionary conserved pathogen-associated-molecular-patterns such as lipopolysaccharides, peptidoglycan, flagellin, double-stranded RNA, and bacterial CpG DNA. Recognition of pathogen-associated-molecular-patterns by TLR leads to activation of NF- $\kappa$ B followed by an increased secretion of proinflammatory cytokines such as IL-6, IL-8, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) leading to killing and clearance of pathogen.<sup>46</sup> Expression of TLR1 to TLR11 in addition to other signaling components such as CD14 and MyD88 have been observed in the male urogenital tract.<sup>47</sup> Activation of TLRs by using various TLR ligands such as CpGA (TLR-9 ligand), poly I:C (TLR-3 ligand), and flagellin (TLR-5 ligand) have been shown to reduce viral infections.<sup>48–50</sup>

**Fig. 25.2:** Mucosal innate immune system in the reproductive tract. The innate immune system provides the first line of defense against a wide range of microorganisms before the development of adaptive immune response. Epithelial cells, and neutrophils secrete molecules like defensins, secretory leukocyte protease inhibitor, lysozyme, lactoferrin, pentraxins, and collectins, which have anti-microbial activity and play a key role as effectors and modulators of innate immune response. Activated macrophages, dendritic cells, and natural killer cells, in turn secrete chemokines, cytokines and components of complement system. Toll like receptors expressed by various reproductive tract associated cells recognize conserved sequences called pathogen-associated-molecular-patterns present on bacteria, viruses, and fungi and hence help in their elimination.

In the intestinal tract, the mucosal immune response is frequently initiated by antigen uptake by microfold (M) cells which overlay the PPs. Since M cells have not been described in the vagina or cervix, it was suggested that the genital mucosa is a poor site for induction of mucosal immune responses. Consequently, local humoral and cellular immune responses stimulated by infections such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, papillomavirus, and HIV-1 are weak or absent, and repeated local intravaginal immunizations result in minimal humoral responses. Because a significant proportion of IgG in genital tract secretions is derived from the circulation, systemic immunization may provide protective IgG antibody-mediated immunity in the genital tract. The female reproductive tract, depending upon its ability to mount an immune response, can be divided into non-sterile and sterile regions. The non-sterile regions include vagina and ectocervix while the sterile region comprises of endometrium, fallopian tube, and endocervix.<sup>30</sup> Assessment of immunoglobulins produced against STIs has shown that the response generated in the mucosal tract of infected persons is comparable to that in uninfected individuals. For example, women diagnosed with gonococcal cervicitis showed low local mucosal IgA and IgG against *Neisseria gonorrhoeae* whether measured in cervical mucus, vaginal washes, serum, or saliva. This showed little or no significant difference from antibodies measured in individuals from the same population who were not infected with *N. gonorrhoeae*. In men with gonococcal urethritis, low levels of antigenococcal IgG and IgA were found and these were not

significantly different when compared to uninfected subjects.<sup>51,52</sup> The poor response to *N. gonorrhoeae* infection is due to the ability of the pathogen to protect itself against the immune response by several mechanisms like extensive and rapid antigenic variation of surface proteins, variation and sialylation of lipopolysaccharides, interference with complement mediated lysis, and the production of IgA1 protease.<sup>51</sup> In the case of HIV, the immune system is not able to mount a response against the virus due to the ability of the virus to evade the immune system by frequent mutations. The antibodies produced against a particular strain become ineffective in preventing infection with another strain. The virus is able to replicate within human cells by binding a human cellular protein (cyclophilin) to its capsid, which blocks the action of the inhibitor restriction factor-1. Within monkey cells, the virus is not able to replicate itself due to the binding of the inhibitor to the capsid of the virus.<sup>53</sup> The limited ability of the reproductive tract to mount an immune response, along with the ability of some of the pathogens to evade the immune system, suggests a need to enhance the mucosal immune response to counter STIs.

### Strategies for Enhancing Mucosal Immune Responses against STIs

The absence of an effective vaccine for the prevention of AIDS and most other STIs has generated renewed interest in augmenting the immune response in the reproductive tract to combat these infections. Vaccination via a mucosal route is a

very attractive option for immunization, because both local and systemic immune responses are inducible and vaccines can be administered easily and safely from infants to elderly persons. Since the genital mucosa is usually the major entry for sexually transmitted pathogens, the focus has been on priming the genital mucosal tract to prevent the infections. In order to generate adequate mucosal immune response against STIs, different strategies like immunization with whole pathogen (live-attenuated or killed) or the use of antigenic epitopes of the infectious agents (protein/protein subunit, polysaccharide, or polysaccharide-protein conjugate) have been adopted.<sup>54</sup> Topical microbicides, self-administered agents designed for vaginal use that block transmission at the mucosal surface, may provide a realistic method of intervention. In addition, different routes of immunization (systemic, oral, rectal, vaginal, tracheal, or nasal) have also been tested to obtain an optimal response.

## IMMUNOGENS

### Whole Pathogen

#### Killed

Killed pathogens have been used as immunogens to prevent STIs and have proved to be successful against other diseases like influenza, polio, typhoid, etc. Many of these vaccines have already been overtaken by new and improved versions, including subunit vaccines and orally active preparations. The use of heat-killed chlamydia was unable to elicit a sufficient immune response to prevent infection. This may be due to the inability of the inactivated organisms to mobilize mature dendritic cells.<sup>55,56</sup> Intrarectal administration of heat killed *Candida albicans* in combination with a mucosal adjuvant LT (R192G), a genetically detoxified form of the heat-labile toxin of enterotoxigenic *Escherichia coli*, in male mice produced anti-*C. albicans* antibodies. These animals were able to eradicate intravenous challenge with *C. albicans* better than the animals immunized with heat-killed *C. albicans* alone.<sup>57</sup>

The use of whole inactivated virus as immunogen has been one of the strategies adopted to develop vaccines against HIV. Initial experiments in macaques with whole killed simian immunodeficiency virus induced sterilizing immunity against the virus.<sup>58</sup> However, subsequently it was observed that the protective immunity observed in these animals was contributed to, at least in part, by the immune response against human cellular antigens.<sup>59</sup>

#### Live Attenuated

Immunogens used in this form are the most successful vaccines currently in use. Many viral vaccines of this type have an efficacy of more than 90%, and protection frequently lasts for many years. Their ability to replicate enables them to induce a full range of immune response including an MHC-class I restricted cellular response. The use of live-attenuated lentivirus “vaccines” has shown best protection from uncontrolled viral replication and

clinical disease after pathogenic simian immunodeficiency virus challenge.<sup>60</sup> However, various safety concerns have prevented the use of such immunogens, primarily due to the fear of reversion to the wild active type.

## Subunit Vaccines

The drawback in using the whole pathogen for generating protective immunity is that the immune response generated is non-specific and this may have adverse effects on the health of the infected person. Hence, the concept of developing subunit vaccines was explored. Intradermal immunization with *Candida albicans* recombinant heat shock protein 90 kDa (hsp90-CA) followed by intranasal or intradermal boosting induced a significant increase in both serum and vaginal hsp90-CA-specific IgG and IgA antibodies. In the intradermally boosted group, subsequent experimental vaginal *Candida* infection induced an additional increase in the hsp90-CA specific IgG isotype, suggesting that specific antibody responses may be generated during vulvovaginal candidiasis.<sup>61</sup> Trichomonads can cause both human and bovine infection. The causative organism in cattle is *Trichomonas foetus*. Immunization of cattle with a surface antigen (TF1.17) provided protection against trichomoniasis.<sup>62</sup> Immunization of rabbits with recombinant *T. pallidum* repeat protein *K* (*TprK*) showed that the lesions developed were smaller, did not ulcerate or have detectable treponemes, and healed more rapidly than the lesions in control rabbits.<sup>63</sup> Further studies using fragments of *TprK* in rabbits showed that of the three fragments tested, fragment 1 (amino acids 37–273) was the most effective in preventing ulceration of lesions. Fragment 3 (amino acids 349–478) had intermediate effects, whereas fragment 2 (amino acids 274–348) was ineffective. These results demonstrate that epitopes in fragment 1 are recognized by T cells, and antibodies are produced during infection. Immunization with this portion of *TprK* therefore most effectively attenuates the development of syphilitic lesions.<sup>64</sup> Conceptually, subunit vaccines should be effective in generating specific immune responses and thereby provide long-lasting protective immunity. In practice though, no single subunit vaccine has yet produced a sterilizing, long-term immunity. The induction of a high level of Th-1 response along with a substantial IgA and IgG antibody response at the mucosal site of infection is a prerequisite for developing protective immunity. This makes the development of a multi-subunit vaccine approach more plausible than the single subunit vaccine approach. Researchers at Antex Biologics (Maryland, USA) are developing TRACVAX, a multi-subunit vaccine based on recombinant subunits of proteins from *Chlamydia trachomatis*.<sup>65</sup> The exact antigen composition of this vaccine is not known, but it is likely to feature chlamydial proteins from a super family known as polymorphic membrane proteins.<sup>65</sup> A further study examined a vaccine composed of a combination of the major outer membrane protein and porin B protein of *C. trachomatis* that have a protective advantage over a single subunit construct. The results showed that significant levels of chlamydia-specific sIgA and IgG2a were detected in vaginal washes and serum of immunized mice, and the multi-subunit

construct induced a significantly higher level of Th1 response than the single subunits as measured by the amount of interferon-gamma produced by immune T cells in response to re-stimulation with ultraviolet-irradiated elementary bodies *in vitro*.<sup>66</sup>

The simultaneous expression of structural proteins of virus can produce virus-like particles (VLPs) by a self-assembly process in a viral life cycle even in the absence of genomic material. Taking advantage of structural and morphological similarities of VLPs to native virions, VLPs have been suggested as a promising platform for new viral vaccines. In order to develop a vaccine for prevention of HPV infection which has implications in the reduction of cervical cancer, it was demonstrated that HPV-16 L1 capsid proteins form highly immunogenic VLPs.<sup>67</sup> Subsequently, scientific efforts from various groups led to the development of prophylactic vaccines composed of self-assembled VLPs of L1 major capsid proteins that are currently in the market: Gardasil (Merck) and Cervarix (GlaxoSmithKline).<sup>68</sup> Cervarix is designed to protect from infection with HPV-16 and HPV-18, which cause 70% of cervical cancer whereas Gardasil, in addition to these also prevent infection from HPV-6 and HPV-11 which cause 90% of external genital warts. Gardasil contains only aluminum hydroxide as adjuvant whereas Cervarix has AS04, which is comprised of monophosphoryl lipid A (MPL), a detoxified form of lipopolysaccharide and aluminum hydroxide. Aluminum salt based adjuvants typically induce Th2 type response, which is important for a VLP based vaccine system. However, MPL activates innate immune responses via TLR molecules and hence can induce a mixed Th1/Th2 differentiation pattern in human T cells.<sup>67</sup> Recently, vaccinations using these VLPs through nasal and oral routes suggested that these may be antigenically stable and provide the possibility of vaccinating large populations with HPV VLPs without using syringes.<sup>69</sup>

Cellular immune response appears to be the key component necessary for clearance of HPV infections and therefore would be the main target of any therapeutic HPV vaccine. HPV therapeutic vaccines focus mainly on E6 and E7 proteins. Several studies have shown that immunotherapy targeting E6 and/or E7 using vaccinia vectors generates strong cytotoxic T-lymphocyte activity and antitumor responses in preclinical studies.<sup>70</sup> In addition, attenuated *Salmonella* and *Bacillus Calmette-Guerin* have also been proposed as safe and immunogenic to develop bacterial vectors for vaccines encoding HPV-16 L1 and E7.<sup>69,71</sup>

## Polysaccharide

Over the last 20 years protein-polysaccharide conjugate vaccines have been developed to protect against the major invasive bacterial diseases of childhood, *Streptococcus pneumoniae*, *Haemophilus influenzae* type b (Hib), and *Neisseria meningitidis*. These vaccines induce a protective immune response to capsulated bacteria that infect the blood stream. This approach has also been tried for the development of vaccines against STD pathogens. A vaccine composed of liposome-mannan complexes of *C. albicans* produced protective antibodies against disseminated candidiasis.<sup>72</sup> A further study showed that immunization of mice with MAb 6.1, a monoclonal antibody specific for b-1, 2-mannotriose in the mannan complex, protected

mice against infection with *C. albicans*, when administered both intravaginally and intraperitoneally.<sup>73</sup>

## Peptide Vaccines

Peptide vaccines can be synthetically prepared and generally include multiple epitopes corresponding to different proteins of a pathogen. The approach can also deal with serotype variation of antigens, epitopes being chosen from multiple strains. Peptide vaccines suffer from the constraint that many antibodies are directed to conformational determinants. In a study using a combination of T-20 (class 1) and (CCIZN17)(3)(class2) fusion peptides, the result provided evidence that these classes of fusion peptides work synergistically in an *in vitro* infectivity assay in inhibiting the entry of primary HIV-1 isolate 89.6.<sup>74</sup>

## DNA Vaccines

DNA vaccines represent a new approach to the control of infectious disease including STIs. DNA immunization offers many advantages over the traditional forms of vaccination. It is able to induce the expression of antigens that resemble native viral epitopes more closely than standard vaccines do, since live-attenuated and killed vaccines are often altered in their protein structure and antigenicity. Plasmid vectors can be constructed and produced quickly and the coding sequence can be manipulated in many ways. DNA vaccines encoding several antigens or proteins can be delivered to the host in a single dose, only requiring a microgram of plasmids to induce immune responses. Rapid and large-scale production is available at costs considerably lower than traditional vaccines, and they are also temperature-stable making storage and transport much easier. Another important advantage of DNA vaccines is their therapeutic potential for ongoing chronic viral infections. DNA vaccination may provide an important tool for stimulating an immune response in HBV, HCV, and HIV patients. The continuous expression of the viral antigen caused by gene vaccination in an environment containing many APCs may promote a successful therapeutic immune response which cannot be obtained by other traditional vaccines.<sup>75</sup>

A variety of DNA prime and recombinant viral boost immunization strategies have been developed to enhance immune responses in humans. The safety and immunogenicity of an HIV vaccine that combines a plasmid-DNA priming vaccine and a modified vaccinia virus Ankara (MVA) boosting vaccine concluded that this HIV-DNA priming-MVA boosting approach is safe and highly immunogenic.<sup>76</sup> A therapeutic DNA vaccine directed to tumor-specific antigens of the HPV can synergistically enhance immune responses for the treatment of cervical cancer.<sup>77</sup> As DCs are the primary mediators of DNA vaccine-induced immune responses, vaccines that modify intracellular or extracellular movement of antigen or other DC properties are able to enhance DNA vaccine potency.<sup>78</sup> Co-administration of E7 containing DNA with DNA encoding antiapoptotic proteins is able to enhance E7-specific immune responses, tumor treatment, and DC survival. To improve delivery and antigenicity of HPV DNA vaccines, the

use of encapsulation of plasmid DNA encoding fragments derived from E6 and E7 of HPV-16 and HPV-18 in biodegradable particles (ZYC101a) has been reported.<sup>79</sup>

## MICROBICIDES

Although immunization to control the spread of STIs would be ideal, there are currently no protective vaccines available against HIV. The clinical trials of the candidate HIV vaccines showed partial protection. Further, drug resistance has been reported for antiretroviral drugs, the only major therapeutic options currently available for treatment of HIV infected subjects. Hence, it is imperative to explore alternate therapeutic options. The development of vaginally/rectally applied topical microbicides that would be effective against a broad range of pathogens has been identified as a high-priority approach to control STIs including HIV. Microbicides are self-administered prophylactic agents that could be applied topically to the vagina or rectum in various formulations, including gels, creams, suppositories, films, or as a sponge or ring that releases the active ingredient over time, and are one of the most promising technologies under development to reduce the risk of contracting STIs including the HIV. They provide excellent potential as a female controlled preventive option which would not require negotiation, consent or even knowledge of the male partner. Microbicides prevent HIV infection by various mechanisms, such as:

- (i) Vaginal defense enhancers, such agents that maintain an acidic pH hostile to HIV. These agents aim to enhance the vaginal natural acidic environment and production of hydrogen peroxide, which are hostile to pathogens. These include BufferGel, Acidform, lime juice, and Lactobacillus. Natural substances such as antimicrobial peptides (gramicidins and magainins), defensins, retrocyclins, bactenecin, and protegrins are other potential compounds that may be developed as vaginal microbicides in the future.<sup>80,81</sup>
- (ii) Non-specific agents, like detergents, disrupt membranes of cell-free HIV as well as infected donor and uninfected host cells. Microbicides in this category include surfactants (Nonoxynol-9, Octoxynol-9, and Mentegol) that disrupt the lipid membrane.
- (iii) Viral membrane binding agents, commonly polyanions that interfere with cell-virus interactions. These microbicides inhibit the attachment of pathogens to the mucosal surface of the target cells. These include sulfated and sulfonated polymers such as Carraguard, PRO-2000, cellulose sulfate. An “invisible condom” (based on a non-toxic polymer-based gel) has also been proposed that also serves as a barrier against viruses and bacteria.
- (iv) Specific host cell binding agents such as CCR5 inhibitors that prevent cell-virus binding with high specificity such as Maraviroc.
- (v) Inhibitors of viral replication such as tenofovir (nucleotide analog) or UC-781 (nonnucleoside reverse transcriptase inhibitor) that act within CD4+ cells to prevent reverse transcriptase activity.

*In vitro* studies of Praneem, an Indian polyherbal microbicide, have shown activity against clinical isolates of *Neisseria gonorrhoeae* and multidrug-resistant *Escherichia coli*.<sup>82</sup> Basant, another Indian polyherbal cream inhibits the growth of WHO strains and clinical isolates of *Neisseria gonorrhoeae*, including those resistant to penicillin, tetracycline, nalidixic acid, and ciprofloxacin, and has pronounced inhibitory action against *Candida glabrata*, *Candida albicans*, and *Candida tropicalis*.<sup>83</sup> It has also displayed virucidal activity against HIV *in vitro*.

There are approximately 60–80 candidate microbicides currently in development. The majority of these have been evaluated using *in vitro* assay systems and some are undergoing preclinical evaluation. Sixteen candidate microbicides have entered the clinical phase of development. Candidate microbicides that have completed efficacy trials such as Carraguard, have failed to prevent HIV infection.<sup>84</sup> Nonoxynol 9 (N9) also showed an increased risk of HIV transmission in the COL-1492 study.<sup>85</sup> The recent disappointing results from the trials of microbicides have prompted a renewed commitment to basic research to develop additional microbicides for more effective prevention of HIV infection and other STIs.

## Routes of Immunization

Immune responses generated against STIs have also been shown to depend on the route of immunization. Exploitation of immunization routes that are effective for induction of mucosal immune responses taking into account our current knowledge of the origin of antibodies and of specific antibody-forming cells in mucosal tissues is likely to reduce the incidence of many sexually transmitted diseases including AIDS. Since the genital mucosa is a component of the common mucosal immune system, various other routes of immunization have been tried apart from immunizing through the genital mucosa. These include oral, systemic, nasal, and recently transcutaneous immunization.<sup>86,87</sup> Transcutaneous immunization induces a mucosal immune response in the female genital tract.<sup>87</sup> Intranasal immunization has been found to give rise to substantial IgA and IgG antibody responses in the human cervico-vaginal mucosae.<sup>88</sup> The rationale for carrying out immunization through different routes was the observation that intraperitoneal immunization of rats with sheep red blood cells induced to IgA and IgG antibodies in the vagina.<sup>89</sup> This observation helps to confirm the presence of a common mucosal immune system, which in an earlier study was shown by an adoptive lymphocyte transfer method.<sup>90</sup> The application of the immunogen through the intranasal route was shown to induce an enhanced immune response in the genital tract. Intranasal immunization of female mice with a recombinant adenovirus vector expressing glycoprotein B (gB) of herpes simplex virus produced secretory and serum derived humoral immune responses in the genital tract. Intranasal immunization induced anti-HSV gB IgA and IgG in vaginal washes of mice, whereas intra-peritoneal immunization induced only IgG, which was serum derived. Intravaginal immunization produced little anti-HSV

gB IgA and only low levels of specific IgG in vaginal washes.<sup>91</sup> Intranasal immunization with glycoprotein 120 depleted HIV-1 immunogen in combination with immunostimulatory CpG oligodeoxynucleotides (ODNs) produced enhanced levels of anti-p24 IgG and IgA antibodies in serum and vaginal washes compared to mice immunized with HIV-1 immunogen alone or with control ODN. Mice immunized intranasally with HIV-1 immunogen plus CpG were protected against intravaginal challenge with a recombinant vaccinia virus expressing HIV-1 gag.<sup>92</sup> Intranasal immunization with a recombinant vaccinia vector capable of expressing glycoprotein D of HSV-1 provided protection against the development of latent trigeminal ganglionic infection when mice were challenged with a sub-lethal dose of HSV by the lip or nasal route.<sup>93</sup> Recombinant adenovirus expressing glycoprotein B of HSV-1, when administered intranasally, provided protection from systemic heterologous challenge.<sup>94</sup> In mice, vaginal application of anti-HSV antibodies prevented infection and visible signs of genital herpes infection at a dose of ~10 ng.<sup>95</sup> In the vaginal epithelium of T lymphocyte depleted mice, HSV-2 infection caused more fulminant infection as compared to the non-depleted ones.<sup>96</sup> A single rectal immunization of female C57Bl/6 mice with live-attenuated herpes simplex virus type 2 lacking thymidine kinase (HSV-2 TK-) was shown to confer HSV-specific cellular and humoral immune responses as well as protection against an otherwise lethal vaginal challenge with a virulent HSV-2 strain. The immunity afforded by rectal immunization with HSV-2 TK- was shown to be independent of sex hormonal influence and the usage of the adaptor protein myeloid differentiation factor 88 (MyD88).<sup>97</sup> Treatment with estradiol of mice immunized with HSV showed better protection and decreased pathology than progesterone-treated group.<sup>98</sup> Female sex hormones not only regulate susceptibility to various STIs but also play an important role in generating protective immunity.

## Strategies to Enhance Mucosal Immune Response

Vaccine delivery is represented by a diverse range of technologies and approaches, which are linked by the objective of improving vaccine performance or potency. Potentially effective delivery vehicles should promote the induction of adequate levels of mucosal T cell and antibody responses that mediate long-term protective immunity. In order to enhance the mucosal immune response, applications of the antigens incorporated in various delivery systems have been tried.<sup>99,100</sup> These include the following:

- (i) **Co-administration of immunogens with adjuvants active at mucosal surfaces** Some non-toxic mutants of the *E. coli* heat-labile enterotoxin (*LTK63*) have been observed to act as strong mucosal adjuvants when administered through intravaginal and intranasal routes in mice. Certain adjuvants, such as cholera toxin and related enterotoxins can promote mucosal cytotoxic T-lymphocytes (CTL) development when administered orally or nasally with soluble proteins and peptides.<sup>101,102</sup>

- (ii) **Coupling immunogens to carrier molecules that promote their uptake at mucosal inductive sites** Mice immunized intranasally with a recombinant chimeric protein consisting of saliva-binding region of *Streptococcus* and A2 & B subunits of cholera toxoid or type II heat labile enterotoxin of *E. coli* elicited a strong serum IgG and IgA response as well as salivary and vaginal responses. It was also observed that the immune response persisted for 1–2 years and could be recalled by booster immunization.<sup>103,104</sup> In another study recombinant influenza A/PR8/34 (H1N1) viruses were generated by insertion of immunodominant T cell epitopes from chlamydial MOMP into the stalk region of the neuraminidase gene. Intranasal immunization of mice with recombinant virus resulted in a strong Th1 response against intact chlamydial elementary bodies. Also, immunized mice enjoyed significant protective immunity by shedding less chlamydia and rapidly clearing the infection. Furthermore, a high frequency of chlamydia-specific Th1 response was measured in the genital mucosa and systemic draining lymphoid tissues within 24 hr after challenge in vaccinated mice.<sup>105</sup>
- (iii) **Expression of antigens in live-attenuated bacterial or viral vectors that can colonize mucosal tissues** Several live vectors of both bacterial and viral origin have been engineered to provide various cytokines to further stimulate or modulate the immune response. Recombinant adenovirus expressing herpes simplex virus glycoprotein B was shown to be an effective vaccine when given intranasally to mice. This induced serum IgG as well as pulmonary IgA anti-glycoprotein B responses and it protected from challenge with the virus.<sup>89,93</sup>
- (iv) **Incorporation of antigens into a variety of microparticulate or adhesive vehicles that are taken up in mucosal inductive sites** Various lipid-based structures with entrapped antigens such as liposomes, immunostimulating complexes, and different types of biodegradable particles based on starch or copolymers of lactic and glycolic acid have been evaluated. In addition, various mucosa-binding proteins, including both classical plant lectins and bacterial proteins such as the binding subunit portions of cholera toxin or *E. coli* heat-labile enterotoxin, to which antigens have been linked either chemically or as gene fusion proteins have been proposed. Protection against *C. albicans* and *C. tropicalis* infection was observed on vaccination with liposome encapsulated *C. albicans* surface mannan.<sup>65</sup> Promising results have recently been reported from the use of so-called pseudoviruses, or VLPs.<sup>67</sup>
- (v) **Targeting lymphocytes induced by the mucosal immune system to the genital tract tissue** The adhesion molecules (addressins) expressed on the endothelium of blood vessels supplying the tissues help in the recruitment of lymphocytes to tissues. These adhesion molecules serve as ligands for the attachment of lymphocytes expressing the receptors that bind to the adhesion molecules. Within the genital tract tissues, the expressed addressins include intercellular adhesion molecule-I

and vascular cell adhesion molecule-I that are known to be specific binding molecules for lymphocytes.<sup>96,106</sup>

## Conclusion

The genital mucosa is the major entry point for various sexually transmitted pathogens. Hence, it is important to bolster mucosa lining the genital tract so as to enable it to combat these infections at the very site of their entry. For this it is important to generate immune responses that can act both locally as well as through the systemic route. One strategy to elicit enhanced genital mucosal immunity can be the use of a multi-subunit vaccine approach. Also, the various routes of application of the immunogen may prove vital in this process. Studies have shown that the nasal route is able to elicit antibodies in the genital tract against various organisms. Apart from the route of application, the conjugation of the immunogen to carrier molecules, like cholera toxin, has shown to induce a better immune response. Another important aspect is to understand the induction of cell-mediated immunity in the genital mucosa, and the mechanism of generation and recall of memory in the mucosal immune system.

## Laboratory Diagnosis of Sexually Transmitted Infections

Krishna Ray

### Introduction

The continuing epidemic spread of human immunodeficiency virus (HIV) and other sexually transmitted infections (STIs) call for the appropriate management of patients with STIs and their sex partners for the effective prevention of HIV infection. Adequate management of STIs includes an early diagnosis and correct medical treatment, which is dependent on case finding through reliable laboratory procedures.

Laboratory services are important for the development and implementation of STI/HIV control programmes in the following areas: (i) programme management, (ii) patient management, and (iii) research on the development of new diagnostic tests, drugs, and control methodologies. The laboratory plays an essential role in epidemiological and microbiological surveys, antimicrobial susceptibility studies, the validation of treatment, and sexually transmitted diseases (STD) case management approaches such as the syndromic approach.

Though the syndromic approach to STD case management enables healthcare workers to successfully manage more patients with STIs, there are limitations to this approach. There is considerable over treatment, which is clearly preferable and more cost effective than under-treatment for many curable STIs. Nonetheless, the approach can be made more specific by the judicious use of laboratory tests. Besides, tests are essential for the diagnosis of asymptomatic patients, such as for the screening of pregnant women for syphilis and screening of individuals for HIV seropositivity during asymptomatic stage.

In the developing world, laboratory services for STIs are often not available, or not accessible. Despite the existence of national policy for antenatal screening to prevent congenital syphilis, the implementation remains low because of lack of screening tools that can be used in primary healthcare (PHC) settings.<sup>1</sup>

The development of new and rapid nucleic acid amplification tests (NAATs) in the last decade has considerably widened the field of laboratory diagnosis of STIs. Introduction of multiplexing in the new methods has facilitated diagnosing multiple agents by a single test. The tests should be evaluated in field situations

to determine sensitivity and specificity and to make them cost effective, especially in the developing countries. This will offer specific treatment for patients without any delay. In this regard, the World Health Organization (WHO) STD Diagnostics Initiative has developed the ASSURED criteria as a benchmark to decide if tests address disease control needs: Affordable, Sensitive, Specific, User-friendly, Rapid and robust, Equipment-free, and Deliverable to end-users.<sup>1</sup>

Use of non-invasive methods for collection of specimens, like vaginal tampons and first void urine (FVU) has been found to be extremely useful especially for the screening of asymptomatic low prevalence populations.<sup>2</sup> In 2006, a National Institute for Health Workshop supported the use of self-obtained vaginal swabs (SOVSs) as specimens for diagnosis of STIs. It concluded that SOVSs are well accepted by women of all ages and perform as well as or better than other specimen types for detection of *Chlamydia trachomatis* (*C. trachomatis*) and *Neisseria gonorrhoeae* (*N. gonorrhoeae*) using transcription-mediated amplification methods (TMA).<sup>3</sup>

Table 26.1 describes the various symptoms of STIs, the individual STIs for which laboratory tests are available, and the ideal specimens required. The collection of specimens constitutes a very important pre-requisite for ideal results. The guidelines for the collection and transport<sup>2</sup> of samples are described below and specific techniques noted.

### Guidelines for Collection and Transport of Specimens

The following guidelines should be considered for the collection and transport of specimens:

- There should be close and frequent discussions between the clinicians, public health managers and the laboratory staff members regarding collection, transportation, and testing.
- The laboratory should provide sterile specimen containers/transport media/culture plates (in the case of *N. gonorrhoeae* culture) to the clinic in advance. The use of leak-proof specimen containers and appropriate swabs is recommended.

**Table 26.1:** Appropriate Specimens and Diagnostic Tests for Common Microorganisms Transmitted Through Sexual Route

Symptoms	Etiological Agents	Test(s)	Specimens
Genital ulcers	<i>T. pallidum</i>	Dark field examination Antigen detection PCR Serology	Fluid from ulcer Swab from ulcer Swab from ulcer Blood
	<i>H. ducreyi</i>	Smear from ulcer, culture, PCR	Ulcer swab Ulcer swab/vesicle fluid
	HSV	Smear from ulcer/vesicle Antigen detection, PCR Serology	Ulcer swab Blood
	<i>C. granulomatis</i>	Impression smear	Tissue biopsy
Urethral or cervical discharge	<i>N. gonorrhoeae</i>	Direct smear, culture Antigen detection DNA tests	Discharge/Swab-Urethral/ endocervical/rectal/ pharyngeal, FVU, SOVS
	<i>C. trachomatis</i>	Culture Antigen detection DNA tests	Swab-Urethral/ endocervical FVU, SOVS
	Mycoplasmas	Culture DNA tests	Swab-Urethral/ endocervical, FVU
	<i>T. vaginalis</i>	Direct wet mount Culture, DNA tests	Urethral discharge /swabs, FVU in males
Vaginal discharge	<i>T. vaginalis</i>	Direct wet mount Culture, DNA tests	Discharge /swab/SOVS
	<i>C. albicans</i>	Direct smear Culture and speciation	Discharge /swab/SOVS
	<i>G. vaginalis</i> & other anaerobic organisms	Direct smear	Discharge /swab/SOVS
Asymptomatic	HIV, HBV HCV <i>N. gonorrhoeae</i> <i>C. trachomatis</i> <i>T. pallidum</i> (latent syphilis)	Serology Serology As above As above Serology	Blood Blood As above As above Blood

FVU, first void urine; SOVS, self-obtained vaginal swab; PCR, polymerase chain reaction; *T. pallidum*, *Treponema pallidum*; *H. ducreyi*, *Haemophilus ducreyi*; *C. granulomatis*, *Calymmatobacterium granulomatis*; *N. gonorrhoeae*, *Neisseria gonorrhoeae*; *C. trachomatis*, *Chlamydia trachomatis*; *T. vaginalis*, *Trichomonas vaginalis*; *C. albicans*, *Candida albicans*; *G. vaginalis*, *Gardnerella vaginalis*; HBV, Hepatitis B virus; HCV, Hepatitis C virus.

- The clinicians/paramedics entrusted with the collection of specimens should have adequate knowledge of standard precautions and should practice them to avoid needle prick and exposure to blood/body fluids.
- Contamination from indigenous commensal flora, e.g., skin microbes, should be avoided to ensure representative sampling.
- Adequate volumes of each specimen should be collected.
- Immediately after collection, each specimen should be labeled with the patient's name, identification number, source, the date and time of collection.
- Transport conditions should be optimal as the pathogens responsible for STIs are usually fastidious and fragile. Hence, procedures detecting viable organisms may give false-negative results. In general, the specimens should be transported rapidly for the recovery of infectious organisms, using nutritive and non-nutritive systems and avoiding excesses of temperature, especially when culture is attempted. When tests for detection of antigen/antibodies are used, transport conditions are usually less stringent.

- In case the laboratory is away from the clinic, specimens should be transported in sealable, leak-proof plastic bags, having a separate compartment for proformae. Blood should always be collected in leak proof, screw capped, plastic containers.

### Interpretation of Diagnostic Tests

The utility of any diagnostic test, that is their ability to detect an individual having a disease or exclude another without disease, can be determined by calculating the sensitivity, specificity, positive predictive value (PPV) or negative predictive value (NPV). Commonly, sensitivity and specificity are determined. Though these are important parameters to determine diagnostic accuracy, their values are limited to estimate probability, for which PPV and NPV may be used.<sup>4,5</sup> However, both these parameters vary with prevalence of the disease in the population and the values determined for one population cannot be applied to another population. The definition and calculation for the individual parameters are shown below:

2×2 Table for calculating parameters for diagnostic accuracy:

		True disease status		Total
		Present	Absent	
Test result	Positive	a	b	a+b
	Negative	c	d	c+d
	Total	a+c	b+d	a+b+c+d

### 1. Clinical Sensitivity

**Epidemiological definition:** Proportion of individuals with the disease which test positive (i.e., proportion of true positives) =  $a/a+c$ .

**Laboratory definition:** The ability of an analytical method to detect very small amounts of the analyte (such as an antibody or antigen).

A test which is highly “sensitive” from a laboratory perspective is also likely to be “sensitive” from an epidemiological perspective.

$$\text{Clinical sensitivity} = \frac{a = \text{True Positive (TP)}}{a+c = \text{TP} + \text{False negative (FN)}} \times 100$$

### 2. Clinical Specificity

**Epidemiological definition:** Proportion of individuals without the disease which test negative (i.e., proportion of true negatives) =  $d/d+b$ .

**Laboratory definition:** The ability of the test to react only when the particular analyte is present and not react to the presence of other compounds.<sup>6</sup>

A test which is highly “specific” from a laboratory perspective is also likely to be “specific” from an epidemiological perspective.

$$\text{Clinical specificity} = \frac{d = \text{True Negative (TN)}}{d+b = \text{TN} + \text{False positive (FP)}} \times 100$$

**3. Positive Predictive Value, or Precision Rate, or Post-Test Probability of Disease<sup>4,5</sup>:** It is the proportion of patients with positive test results who are correctly diagnosed. It is the most important measure of a diagnostic method as it reflects the probability that a positive test in an individual reflects that he/she has the disease being tested for. The PPV does however depend on the prevalence of the disease, which may vary and therefore the results should be carefully evaluated to ensure that the disease prevalence is same as that found in the patient population to which the results will be applied.

$$\text{PPV} = a/a+b = \text{True positive/True positive} + \text{False positive}$$

**4. Negative Predictive Value:** It is the probability that if the test result is negative, the individual does not have the disease of interest. As mentioned under PPV, NPV also is sensitive to the prevalence of the disease in the population.<sup>4,5</sup>

$$\text{NPV} = d/c+d = \text{True negative/True negative} + \text{False negative}$$

**5. False Positivity Rate (FPR) =  $b/b+d$ :** It is the probability that an individual will have positive test result, though he/she does not have the disease of interest. It is complimentary to clinical specificity.

**6. False Negativity Rate (FNR) =  $c/a+c$ :** It is the probability that an individual will have negative test result though he has the disease of interest. It is complimentary to clinical sensitivity.

## Quality Assurance (QA)

Microbiological investigations are necessary in the diagnosis, treatment, and surveillance of STIs and policies regarding the selection and use of antimicrobial drugs. It is, therefore, important that test reports are relevant, reliable, timely and interpreted correctly. QA has been defined by WHO<sup>7</sup> as the total process whereby the quality of laboratory reports can be guaranteed. It has been summarized as the right result, at the right time, on the right specimen, from the right patient, with the result and interpretation based on correct reference data, and at the right price.

QA is the total process whereby the quality of laboratory reports can be guaranteed.

It must be borne in mind that the quality of microbiological reports is fundamentally dependent upon the (i) quality of the specimen submitted, (ii) nature and timing of specimen, (iii) the suitability of sampling method and transport, (iv) use of transport media, and (v) transit time, and (vi) adequacy of information given to the laboratory.<sup>8</sup>

## Quality Control (QC)

The term QC covers that part of QA, which concerns the control of errors in the performance of tests and verification of test results. QC must cover all aspects of each procedure within the department. It must be practical, achievable, and affordable. All materials, stains, media, reagents and kits, equipments, and procedures must be adequately controlled. Supervisory and technical personnel should be well-qualified. Each laboratory must have standard operating procedures (SOPs) in which QA of preanalytical (while collecting specimens), analytical, and post-analytical (reporting and interpreting test results) stages of microbiological procedures should be incorporated. Laboratory personnel need to be aware of the errors that can occur during these procedures.

The laboratory should regularly have internal quality assessment (IQA) and participate in external quality assurance schemes (EQAS).

**IQA:** Each laboratory reporting results of tests should have an IQA system. This can be carried out by regular use of certified reference material as internal as well as external controls, replicate testing, retesting of retained items, and correlation of results of different characteristics of an item.<sup>8</sup>

**EQAS:** It should include testing for important pathogens using reference materials as controls. It should not be too complicated,

costly, or time consuming. Although steps may be taken in a laboratory to ensure the reliability of test results, a system of assessing a laboratory to do this to a satisfactory standard is recommended, i.e., an EQAS. Participation in EQAS should always be regarded as additional to internal QC which can assess only past performance when test results have already been reported and acted on.

The main objectives of an EQAS are to confirm that a laboratory's SOPs and internal QC procedures are working satisfactorily to help to identify errors, to improve the quality of work, stimulate staff motivation, to assure patients that the laboratory is performing to the standard required and to provide reliable results.

When comprehensive control measures and relevant assessments are in place, a laboratory can claim a level of quality assurance. QA can be seen as the sum of QC, IQA, and EQA, i.e.,  $QA = QC + IQA + EQA$ .

The diseases for which laboratory methods are useful tools have been described under:

- I. Presenting with genital ulcer
- II. Presenting with genital discharge
- III. Others

## Genital Ulcer Disease

### SYPHILIS

Syphilis, an infectious STD, is distributed worldwide. In developing countries, it is one of the leading causes of genital ulcer disease (GUD). It is caused by a spirochaete, *Treponema pallidum* (*T. pallidum*), subspecies *pallidum*. The other pathogenic species in the genera that do not produce STIs are *Treponema pertenue* causing Yaws, *Treponema carateum* causing Pinta, and *Treponema endemicum* causing endemic syphilis. The above four species cannot be differentiated morphologically or by antigenic characteristics, but only by their clinical and epidemiological features.<sup>9</sup> The infection is acquired by direct sexual contact with lesions of primary and secondary syphilis and by unsafe blood transfusion. Transplacental transmission to the fetus *in utero* is common in developing countries. The disease is systemic and the natural course of the infection may span several decades. Although syphilis is treatable, it increases HIV transmission by 3–5 fold.<sup>10</sup>

### Laboratory Diagnosis

The laboratory plays an important role in screening and confirmation of clinical syphilis. The choice of the laboratory tests varies according to different stages of the infection. HIV seropositive patients acquiring syphilis may fail to produce antitreponemal (anti-TP) antibodies or may show delayed seropositivity. Therefore, negative syphilis serology in HIV seropositive patients does not necessarily exclude a syphilitic infection.<sup>11</sup>

### Laboratory Methods

Direct demonstration of *T. pallidum* or its products like Antigen/DNA in the lesions.

### Demonstration of *T. pallidum*

**Dark Field (DF) Microscopy** A potentially sensitive and specific method for confirming the diagnosis of primary syphilis is direct demonstration of treponemes with characteristic morphology and motility, in the fluid obtained from the surface of the chancre by DF microscopy.<sup>12</sup> The test is very useful in primary and secondary syphilis and also in cases of congenital syphilis. The treponemes should be viable to distinguish *T. pallidum* from morphologically similar saprophytic spirochaetes present in the genital area.

Preparations must be examined immediately after the specimen is obtained. The result depends on the proper collection of specimen, expertise of the microscopist, and the exclusion of previous therapy with antibiotics, local or systemic. Two DF smears should be collected, as a single DF examination has sensitivity of not more than 50%.<sup>12</sup> If topical antibiotics have been used for treatment, or the ulcer has dried, material obtained by lymph node aspiration should be examined or other antigen detection methods used.

**Collection of specimen:** The lesions are cleaned carefully with gauze and saline followed by abrasion with dry gauze and gentle squeezing to get a serous exudate. Cleaning with soap or disinfectants should be avoided, only a minimum amount of tap water or saline may be used. In case of bleeding, the blood is wiped away and serous fluid collected directly on a coverslip or on a clean slide by pressing the slide directly on to the lesion. The coverslip is positioned on to the slide. Two slides are collected for better sensitivity. In case the fluid is scanty, it may be mixed with a drop of saline to give a homogenous suspension. The slide is examined immediately under a DF microscope in the laboratory adjacent to the clinic and cannot be transported to a distant laboratory, as examination of motility is important in interpretation. Biosafety precautions should be taken in handling and in discarding the waste material.

### Principle of DF microscopy and method of examination:

In DF microscopy, only light rays striking the treponemes at an oblique angle enter the microscope objective through the DF condenser, producing a luminous appearance against a dark background. Usually, the examination is done in a dark room. A few drops of immersion oil are put on the condenser, which is slightly lowered and centered. After placing the slide on the stage, the condenser is raised so that the oil touches the bottom of the slide, the end point being the illumination of the slide. After focusing under low power (10×), the material is examined under high power (40×) and then under the oil immersion lens.

**Microscopic appearance:** *T. pallidum* appears as white, very delicate organism, 0.1–0.18 µm in width and 6–20 µm in length, on a dark background.<sup>9</sup> It has 8–14 regular, tightly wound spirals with pointed and tapering ends. Motility is quick and abrupt, showing corkscrew rotation, bending, forward and backward movement, twisting, buckling, expanding, and shortening.

*T. pallidum* should be differentiated from atypical spirochaetes which are surface organisms and are not found in the depth of

lesions. These are thick, coarse, and loosely coiled. Their movement is writhing with a marked flexion and frequent relaxation of coils. Because of the presence of commensal organisms, DF examination is not recommended for oral, rectal, and non-penile genital lesions.<sup>9</sup> It is also not recommended for evaluating dry sores.

The presence of treponemes with characteristic morphology and motility confirms the diagnosis of early syphilis, even with negative serology. However, failure to find the organisms does not exclude the diagnosis of syphilis, as a DF examination may be negative due to various factors.<sup>12</sup>

**Identification of *T. pallidum* in Lesion Biopsy** In the presence of clinical symptoms suggestive of syphilis, even with negative serology, a tissue biopsy examined by immunofluorescence<sup>13</sup> or the silver impregnation stain of smears may demonstrate the treponemes.

### Detection of Antigen

**Direct Fluorescent Antibody Test (DFA–*T. pallidum*)** This test eliminates the hazards of examining infectious specimens as living, motile treponemes are not required. The test is 100% specific, differentiating *T. pallidum* from non-pathogenic treponemes. It is usually performed on lesion exudates, including rectal and oral lesions, tissues and also body fluids. After collecting specimens from lesions as in DF microscopy, the dried slide is fixed with acetone and stained with the fluorescein-labeled anti-*T. pallidum* monoclonal antibody. The visualization of apple green colored spirochaetes under fluorescent microscope (FM) gives a specific diagnosis.<sup>13</sup>

**Enzyme Immunoassay (EIA)** This test, developed commercially, detects *T. pallidum* in early lesions without the help of a microscope (Visuwell Syphilis antigen EIAADI Diagnostics).<sup>14</sup> The material collected on a swab is used to extract the antigen, which is captured by a *T. pallidum*-specific monoclonal antibody. The sensitivity of the test is comparable to DF examination but it lacks specificity.<sup>15</sup>

### DNA Investigation

DF microscopy is still considered the standard test of choice to demonstrate *T. pallidum* in exudates of mucocutaneous lesions of early syphilis and serology is also a valid tool for the clinician for diagnosis and management. However, in certain cases, evidence of the presence of DNA segments of *T. pallidum* can be used for the confirmation of the diagnosis, especially when associated with HIV infection.

**Polymerase Chain Reaction (PCR)** A sensitive, specific, and robust PCR method<sup>16</sup> reacts with various pathogenic *T. pallidum* subspecies but not with the non-pathogenic species or other spirochaetes. It compares well with a multiplex-PCR (M-PCR) test for *T. pallidum*, *Haemophilus ducreyi* (*H. ducreyi*), and herpes simplex virus (HSV).<sup>17</sup> The test is useful even in the presence of HIV infection. Clinical diagnosis and reactive syphilis serology

are less sensitive and specific than M-PCR.<sup>18</sup> It is valuable in diagnosing congenital syphilis, neurosyphilis (the serologic test available presently is only 50% sensitive), early primary syphilis and also in distinguishing new infections from old infections.<sup>19</sup> Despite its high cost, it is very useful to confirm a suspected chancre, if DF microscopy cannot be performed and serology is still negative or difficult to interpret (as in reinfection). The test can also confirm the histopathologic diagnosis of early syphilis, if a small portion of frozen tissue is available. In primary syphilis, PCR is positive exclusively in ulcerative swabs but not in blood specimens, while in secondary syphilis, 50% of the blood specimens are positive by PCR.<sup>20</sup> DFA and PCR perform equally well for detection of *T. pallidum* on touch preparations of genital lesions.<sup>21</sup>

### Serological Tests to Demonstrate Antibodies

Serology remains the mainstay of laboratory testing for syphilis, except during the very early stage of infection. Serological screening for syphilis is mandatory because there is a latent stage of infection, serious adverse effects occur if cases are not diagnosed, and relatively cheap tests and effective therapy are usually available for control.

**Natural Course of Infection and Serological Response** The natural history of syphilis is highly variable in treated and untreated cases. In untreated individuals, the course of the infection is spread over many decades and the clinical presentations are classified into early and late stages. During the course of the disease, antibodies are produced against a variety of antigens, both treponemal (TP) and nontreponemal (non-TP). Specific anti-TP IgM appears towards the end of the second week of infection; anti-TP IgG can be demonstrated later, at about 4 weeks<sup>22</sup> and symptoms also develop around that time. The immune response can be affected by treatment and by HIV infection. Following treatment of early syphilis, the titers of non-specific antibody and specific IgM decline rapidly, but specific IgG antibodies generally persist. HIV infection may reduce or delay the antibody response in primary syphilis, but in most cases the response is exaggerated.<sup>10</sup>

An important principle of syphilis serology is the detection of TP antibody by a screening test, followed by a confirmatory test. The latter should ideally have equivalent sensitivity and greater specificity than the former and be independent methodologically to reduce the chance of coincident false positive (FP) reactions. A second specimen should be tested to confirm the results obtained from the first specimen and to ensure that the patient details on the specimen are correct. A quantitative non-TP test and/or detection of specific TP IgM may be useful to assess the stage of infection and to monitor the effect of treatment. Serology cannot distinguish between the different treponematoses (syphilis, yaws, pinta, and bejel).<sup>22</sup>

The tests may be divided into two categories, depending upon the type of antigen used:

1. **Tests to detect non-TP antibodies/reaginic antibodies/non-specific tests:** These tests essentially employ a non-TP

antigen having cardiolipin, lecithin, and cholesterol,<sup>14,23</sup> and are rapid and simple to perform. Cardiolipin is a complex diphospholipid, widespread in nature,<sup>14</sup> and can be isolated from many mammalian tissues as well as from *T. pallidum*. Due to the host response to lipoidal material released from the damaged host cells and the cell surface of treponemes, anti-lipid IgG and IgM antibodies are formed which are detected by a flocculation test. The test becomes positive 10–14 days after the appearance of chancre and antibody titer gradually increases with time.

During primary syphilis, the reaginic antibodies are present, often at a relatively low level, 1:1–1:4, in about 40% of the patients; whereas in secondary syphilis, only 11% had these low titers.<sup>24</sup> The titer diminishes after treatment and the test tends to become negative over 6–8 months.<sup>23</sup> It is also negative during late syphilis. The occurrence of the “prozone phenomenon” in secondary syphilis,<sup>25</sup> results from an excess of antibody preventing antigen–antibody binding. This limits its sensitivity and therefore screening with a non-TP test alone is not recommended. The importance of repeat testing is well founded because some patients with primary syphilis will be seronegative at initial presentation.<sup>26</sup> Reactive screening tests should be confirmed with a TP test, different from that used in screening.<sup>22</sup>

There are a variety of non-TP tests, like Venereal Disease Research Laboratory (VDRL) and Rapid Plasma Reagin (RPR) test and its modification, Toluidine Red Unheated Serum Test (TRUST).<sup>27</sup> All the tests are performed using serum but can also be carried out on cerebrospinal fluid (CSF). RPR can be tested with plasma.

(i) **VDRL test:** It is a micro-flocculation test for syphilis using an antigen containing cardiolipin, lecithin, and cholesterol and has to be prepared daily. The test is usually performed as a slide test in which the serum of the patient, inactivated at 56°C for 30 minutes, is mixed with freshly prepared cardiolipin antigen, the mixture rotated mechanically for 4 minutes at 160 rpm and flocculation is detected microscopically using the low power objective. Quantitative tests using the serial dilution of the serum are also done. The test is cost-effective, rapid, simple to perform, and valuable. It can also be used as a prognostic test, as the titer declines with treatment. VDRL was reactive in approximately 75% of patients with primary syphilis, in 100% with secondary syphilis, and in 96% with latent syphilis, and was 98% specific.<sup>23,24</sup> The antigen is now synthesized,<sup>28</sup> which offers advantages in its standardization and stability.

(ii) **RPR test:** It is a field level screening test and has several advantages over the VDRL such as:

- use of stabilized antigen (6 months at 4–10°C), which need not be prepared daily.
- use of disposable printed cards instead of glass slides.

- addition of finely divided charcoal particles to the cardiolipin antigen, helping in naked eye examination of results.
- inactivation of serum is not required and the test may also be carried out with plasma.
- possibility of automation for use in centres where large numbers of sera are tested.

A modification of the test, RPR Teardrop test enables finger prick blood samples to be tested, and is ideal for field conditions.

(iii) **TRUST:** In this modification of RPR, toluidine red is used as a toner, thus obviating the need of a microscope. The sensitivity and specificity of VDRL and RPR tests and TRUST are similar.<sup>27</sup>

### **Biological false positive (BFP) reaction with non-TP tests:**

Since antibodies against a non-specific antigen shared by treponemes and normal tissues are detected in these tests, positive results are occasionally found in the sera of healthy individuals (1–2%) or patients without any clinical evidence of syphilis. These BFP reactions are labeled as acute if they disappear within 6 months and chronic if they persist longer. Acute BFP reactions are usually found in acute febrile infectious diseases, while chronic BFP reactions show a high incidence in autoimmune and related disorders and in drug addicts. VDRL test was reported to have 26% BFP reaction, significantly higher in women than in men and a 10-fold higher rate in HIV-seropositive patients.<sup>29</sup> BFP reaction is often encountered in pregnant women, leading to over-treatment. BFP-RPR reaction was found in 15% and 1.2% of HIV infected and non-infected patients, respectively.<sup>30</sup> Reactive VDRL/RPR results therefore need to be confirmed with *T. pallidum*-specific tests, which are technically demanding and not widely available in most developing countries. There is a need for simple, rapid, point-of-care (POC) type *T. pallidum*-specific test.<sup>1</sup>

2. **Tests to detect TP-IgG antibodies (Specific tests):** These tests use *T. pallidum* antigen to detect specific antibodies against *T. pallidum* cellular components. Currently, three different tests are employed as follows:

(i) ***Treponema pallidum* hemagglutination assay (TPHA/MHA-TP):** It is the easiest to perform and was the first of the specific tests used for routine screening. Red blood cells (RBCs) are treated to adsorb sonicated treponemes on their surface. When mixed with sera containing anti-TP antibodies, the cells are clumped. The sensitivity is 82% (69–90%) in primary syphilis. A negative TPHA result in the primary stage does not exclude syphilis. Positivity remains for life in most of the patients. It is a convenient test and a large number of sera samples can be tested at one time. Occasional false positive (FP) results have been reported, which could represent the effect of previous infection with endemic treponematoses.<sup>14</sup>

Fig. 26.1: FTA-Abs test.

(ii) **Fluorescent treponemal antibody absorption (FTA-Abs) test:** This is the most widely used test employing indirect immunofluorescence (IIF) using killed TP antigen (Nichol's strain) on a slide + patient's serum + labeled anti-human gamma globulin. The cross-reacting antibodies are removed from the patient's serum by absorption with a non-pathogenic TP antigen. The slides are examined under a fluorescing microscope (FM) for the presence of fluorescent treponemes (Fig. 26.1). It has previously been considered the most sensitive and specific of all the TP tests at all stages of syphilis. It is technically difficult to perform, and requires good quality reagents, an expensive FM and experienced microscopists. It cannot screen a large number of slides at one time. Its sensitivity and specificity are lower than that of certain other TP tests,<sup>26,31</sup> occasionally giving equivocal and false-negative results.<sup>32</sup> It is not recommended now as the first line confirmatory test.

(iii) **EIA:** This test has comparable sensitivity and specificity to the above two tests and is an appropriate alternative to the combined screening of VDRL/RPR and TPHA.<sup>20,25</sup> There are several different EIAs<sup>33,34</sup> based on different principles and different antigens (sonicates or recombinant proteins). The Captia Syphilis-G-EIA<sup>33</sup> is a single readily automated screening test in which the antigen coated on micro wells is detected by a tracer complex containing monoclonal antibody. The sensitivity and specificity are less than the FTA-Abs assay. The sensitivity is higher than TPHA in primary syphilis.<sup>34</sup> Certain newer EIAs,<sup>35–38</sup> based on recombinant antigens, are highly specific and sensitive for screening of syphilis at all stages and are significantly more sensitive than the FTA-abs. A novel immuno-capture EIA (ICE Syphilis; Murex Diagnostics, Dartford, UK), using three recombinant *T. pallidum* antigens detects more syphilitic infections in patients co-infected with HIV than does the Captia Syphilis-G EIA.<sup>38</sup>

### 3. New tests:

- (i) **Particle agglutination test (TPPA):** A Serodia TPPA test<sup>39</sup> using gelatin particles rather than RBCs as a carrier, agrees well with MHA-TP and some EIAs mentioned above, and can be used in conjunction with the RPR test.<sup>40</sup> TPPA also agrees well with a new syphilis fast latex agglutination test taking only 8 minutes to perform.<sup>41</sup>
- (ii) **Particle gel immunoassay (ID-PaGIA syphilis antibody test, Diamed):** The sensitivity of this recombinant TP antigen-based test is comparable to that of other TP tests and the specificity is even better. It is fast (reaction time of only 20 min), simple and needs minimal technical equipment.<sup>42</sup>
- (iii) **Whole-blood hemagglutination inhibition test for VDRL antibodies:** Antibody to human RBCs conjugated to VDRL liposome reacts with a diluted sample of patient's whole blood. The test has very high sensitivity and specificity, and has potential for POC testing in developing countries.<sup>43</sup>
- (iv) **Western blot (WB):** IgG WB uses a lysate of whole *T. pallidum*.<sup>44</sup> Keeping clinical diagnoses as the reference method, it has higher sensitivity and specificity than both FTA-Abs and TPHA. The agreement between WB and TP-PA is significantly better (61.5%) than that between WB and FTA-Abs (38.5%). It is a useful additional confirmatory test.
- (v) **Line immuno assay (LIA):** The sensitivity and specificity of this test is very high when compared with TPHA and IgG-FTA-Abs,<sup>45</sup> and may be used as a confirmatory test.
- (vi) **Chemiluminescence immunoassay (CLIA):** LIAISON CLIA TP Screen (DiaSorin, Saluggia, Italy), a new automated assay, demonstrates excellent sensitivity and specificity when evaluated both as a confirmatory as well as a screening test.<sup>46</sup> The Architect CLIA, another new highly automated test, is significantly more sensitive than the Murex ICE screening EIA in detecting primary syphilis, but it is significantly less specific.<sup>47</sup>
- (vii) **Immunochromatographic assay (ICA):** With TPHA results as the reference, sensitivity and specificity of the Abbott Determine Rapid Syphilis ICA are very high with minimum inter-reader variation.<sup>48</sup> However, compared to two EIAs, the sensitivity and specificity of another rapid, one step ICA, are too low to implement the test in a hospital laboratory in a developed country, but it might be useful in developing countries.<sup>49</sup>
- (viii) **Automated immunoassays:** Two automated immunoassays, Enzygnost Syphilis and ARCHITECT Syphilis TP, offer a good choice as screening tests, compared to TPHA and homemade WB. However, the use of confirmatory tests is necessary to avoid FP results.<sup>50</sup>

4. **IgM antibody tests:** In syphilis, TP-IgM antibodies appear early and can be present during late and latent syphilis. Positive IgM reactions are considered to be consistent with recent/active TP infection. The antibody level decreases after spontaneous cure and usually disappears within 6–12 months after therapy, depending on the stage of the disease. *T. pallidum*-specific IgM antibodies do not cross the placenta, and their presence in the blood of the newborn indicates congenital syphilis. Its presence in cerebrospinal fluid (CSF) with an intact blood-brain barrier indicates neurosyphilis.

Different techniques have been utilized for the detection of serum IgM antibody in syphilis and are especially useful in the diagnosis of early primary, neuro and congenital syphilis. The Captia Syphilis-M EIA has a sensitivity of 93% in primary, 85% in secondary, and 64% in early latent infection.<sup>51</sup> However, in primary stage, DF examination is a rapid and sensitive test allowing immediate diagnosis, treatment, and partner notification to prevent further transmission. EIA-IgG takes longer to become positive and is less sensitive.<sup>52</sup> The IgM capture EIA, detecting anti-TP IgM by m chain capture,<sup>53</sup> is easy to perform and is highly sensitive in detecting early infection compared to 19S IgM FTA-Abs. The Mercia IgM EIA<sup>54</sup> is as sensitive as VDRL test in monitoring treatment of primary syphilis, but not in patients treated for secondary syphilis or early latent infection. *T. pallidum* IgM immunoblot (IB) is another sensitive method to detect congenital syphilis.<sup>55</sup> A combination of routine EIA and WB-IgG and IgM may be a valid strategy for confirmatory diagnosis.<sup>56</sup>

5. **Neurosyphilis:** *T. pallidum* invades the central nervous system (CNS) in 25% of patients with syphilis<sup>57</sup> and infection is cleared from there in majority of these cases. But the remaining patients remain at risk for developing sequelae of neurosyphilis of varying degrees of severity and therefore it is necessary to perform tests with CSF. Risk factors for development of neurosyphilis in presence of HIV infection are either CD4 count of  $\leq 350$  cells/mm<sup>3</sup> or serum RPR titer  $\geq 1:32$ .<sup>58</sup>
6. **Tests on CSF:** Usually, a negative TPHA result on sera samples in patients without any clinical suspicion of neurosyphilis rules out the diagnosis. However, positive TPHA results, along with some clinical signs and symptoms, warrant a detailed examination of CSF to exclude the early invasion of the CNS. In addition to a cell count ( $> 5$  cells/ $\mu$ L), VDRL, TPHA, and FTA-Abs tests are indicated for CSF. The sensitivities of VDRL and RPR tests are only 70.8% and 75%, respectively but the specificities are very high for current neurosyphilis cases.<sup>59</sup> Therefore, only the detection of treponema-specific IgM antibodies can provide a confirmatory diagnosis of neurosyphilis. The INNO-LIA Syphilis Score<sup>60</sup> detects specific anti-treponemal antibodies in the CSF of patients with tertiary stage of syphilis.

**Table 26.2:** Possible Pattern of Laboratory Test Results in Acquired Syphilis

Interpretation	DF	VDRL/ RPR	TPHA	FTA- Abs	EIA	IgM test
Primary	+	+/-	-	+	+/-	+
Secondary	+	+	+	+	+	-
Untreated early latent	-	+	+	+	+	-
Late or late latent	-	-	+	+	+	-
Treated/partially treated	-	+/-	+	+	+	-
False +ve	-	+	-	+/-	-	-

**Interpretation of serological tests:** Reports vary on sensitivity and specificity of the available serological tests. Their results in different stages and their interpretations are given in the Table 26.2. For routine screening for syphilis, a non-TP test with confirmation by a TP test is recommended.

A non-reactive serology in the presence of clinical symptoms with a negative DF test indicates that the patient should be followed up. If treatment is started early on the results of positive DF test, the patient may remain antibody negative. However, non-reactive results for non-TP or TP tests, in the absence of clinical symptoms and HIV seropositivity, have a high negative predictive value for excluding current or previous syphilitic infection.

A reactive non-TP test indicates present infection, treated or untreated recent infection, or BFP result, which are always in  $< 1:4$  dilutions. Therefore, a titer of 1:8 or above is always diagnostic. All the low-titer positive sera in non-TP test should be confirmed by a TP test. A positive TP can indicate past infection, since patients infected with *T. pallidum* can remain positive for TP antibodies for years. Low titers in non-TP tests do not exclude syphilis and may be found in very early cases, latent or late syphilis.<sup>24</sup> Titers less than 1:4 with typical clinical signs and symptoms are considered as diagnostic of early syphilis and should be treated accordingly. The quantitative testing of VDRL should always be done. This is important in the follow-up of patients after treatment and also to obviate the problem of prozone phenomenon. However, careful interpretation of the clinical and laboratory results in each case is recommended to avoid serious social and medical implications. Whenever necessary, the test should be repeated with a fresh sample.

## CHANCROID

Chancroid is an acute highly contagious STD, associated with multiple painful genital ulcers, bubo formation, and suppurative inguinal lymphadenitis. It is common in tropical countries and is caused by *H. ducreyi*, a gram-negative, non-motile, coccobacillus ( $1.2 \mu\text{m} \times 0.5 \mu\text{m}$ ) with rounded ends. Mixed infections are common, and HIV seropositive and other immune-compromised individuals may have atypical presentations.<sup>61</sup> Therefore, the clinical diagnosis of chancroid is not very reliable (accuracy of 33–80%).<sup>62</sup> Laboratory confirmation is required for better diagnosis, especially in chancroid endemic regions of the world.

## Laboratory Diagnosis

This is based on the identification of *H. ducreyi* from genital ulcers or bubo material, and by the exclusion of other causes of genital ulcers producing a similar syndrome (Table 26.1). The direct smear examination is insensitive.

**Collection and transport of specimen:** Specimens for bacteria/antigen detection include material from ulcer and/or bubo aspirates. The ulcer is cleaned with a dry gauze or a swab to remove crusts and superficial debris by flushing with sterile physiological saline.<sup>63</sup> The specimen is collected from the base of the purulent ulcer with two sterile swabs, either cotton or calcium alginate, or by using a sterile plastic loop.<sup>64</sup> The first swab is used for smear examination, and with the second, culture media are immediately inoculated and incubated. The organism only survives for 2–4 hours on a swab at room temperature and longer at +4°C.<sup>65</sup> If clinical specimens are to be transported, a transport medium containing thioglycollate, haemin, l-glutamine, bovine albumin fraction V, and vancomycin 3 mg/L may be used.<sup>63</sup> *H. ducreyi* may remain viable in this medium for at least 24 hours at room temperature or as long as 7 days at +4°C. Amies transport medium may also be used.<sup>63,65</sup> Organisms are usually not seen in bubo pus and the culture from these sites is usually sterile. *H. ducreyi* is known to be fastidious for growth.

## Laboratory Methods

Direct non-culture detection techniques.

### Direct Microscopy

The direct examination of Gram-stained smear has been used with different degrees of success. To maintain the morphology of the bacteria, a rolled smear has been recommended. The first ulcer swab is rolled 180° on a clean glass slide and stained with Gram stain. The typical features of gram-negative slender coccobacilli, either intracellular within the pus cells or more often extracellular, singly, in long parallel chains, along the mucus threads (referred to as 'railroad tracks'), in short chains ('school of fish') or in small clusters are observed (Fig. 26.2).<sup>66,67</sup> The sensitivity of the test is around 50% or less.<sup>61,65</sup> False positive results are expected

**Fig. 26.2:** Gram-stained smear of genital ulcer showing intra- and extracellular *H. ducreyi*.

because of poly-microbial flora, often observed in genital ulcers.<sup>61</sup> The Gram stain of bubo pus is not very sensitive.<sup>68</sup>

### Detection of Antigen

**Direct Immunofluorescent (DIF) Technique** Testing of ulcer material using an *H. ducreyi*-specific monoclonal antibody appears to be useful.<sup>63,68,69</sup>

**Limulus Amoebocyte Assay** An antigen detection assay to detect *H. ducreyi* lipooligosaccharide (LOS) using a LOS-specific monoclonal antibody and an adaptation of the limulus amoebocyte assay has been described,<sup>70</sup> which has better sensitivity and specificity.<sup>63</sup> However, the reagents are not commercially available.

### DNA Investigation

**DNA Probe** The test has shown 100% sensitivity and specificity<sup>71</sup> but its usefulness in clinical practice has still to be fully evaluated.

**PCR** Compared to culture, the sensitivity of PCR is more than 95%.<sup>72,73</sup> A M-PCR technology for the detection of genital ulcer pathogens like *H. ducreyi*, HSV, and *T. pallidum* has been found to be very useful.<sup>17</sup> Two rapid multiplex real-time PCR (M-RT-PCR) reactions for *H. ducreyi*/*T. pallidum* and HSV-1/HSV-2 in ulcer swabs from persons with symptomatic genital ulcers<sup>74</sup> have shown good sensitivity and are reproducible.

### Isolation of *H. ducreyi*

Culture is the gold standard in the laboratory diagnosis of chancroid and provides an isolate for antimicrobial sensitivity testing, which provides useful information in the event of treatment failure. However, the advent of more sensitive DNA amplification techniques has demonstrated that the sensitivity of *H. ducreyi* culture is only about 75%<sup>75</sup> and many laboratories do not have facilities and adequate experience in isolating the organism. For isolation, ulcer material is optimal, followed by recently ruptured bubo exudate, while exudate from an intact bubo is least sensitive.<sup>63</sup> Ideally, the specimen should be inoculated at the bedside onto two media.<sup>76</sup>

**Culture Media and Inoculation** Various media have been compared for their suitability for the isolation of *H. ducreyi*.<sup>76–78</sup> For primary isolation, the highest sensitivity is shown by a gonococcal agar (GCA) base containing 1–2% hemoglobin, 5% foetal bovine serum, and 3 mg/L of vancomycin. Enriched Mueller Hinton chocolate agar is also a good substitute.<sup>64</sup> GCA base containing 0.2% activated charcoal, 1% bovine hemoglobin, 1% CVA enrichment, and 3 mg/L of vancomycin has also been reported to be a cheap and reliable single medium for primary isolation of *H. ducreyi*.<sup>79</sup>

The second swab collected from the ulcer base should be inoculated immediately into culture media and incubated at 32–34°C in a moist atmosphere for at least 48 hours and up to 7 days in the presence of 5–10% of CO<sub>2</sub>.<sup>80</sup> Typical colonies are

pin-point in size at 24 hours and 1–2 mm in diameter at 48–72 hours. They are yellowish or grayish yellow, raised, granular, semi-opaque, difficult to emulsify, and can be pushed across the surface of the agar with a loop.

**Identification of Colonies** The colonies are identified by a combination of the oxidase test, nitrate reduction, porphyrin test for haemin requirement and others.<sup>81</sup> *H. ducreyi* may produce beta-lactamase.

### Antimicrobial Resistance (AMR)

Clinically significant high-level plasmid-mediated AMR, spreading rapidly, has been reported in *H. ducreyi*,<sup>82,83</sup> necessitating adequate antimicrobial surveillance. AMR was reported to ampicillin, sulfonamides, chloramphenicol, tetracycline, streptomycin, and kanamycin. However, *H. ducreyi* is very sensitive to quinolones, macrolides like erythromycin or azithromycin, and the third generation cephalosporins. Most of the published studies have used the agar plate dilution technique to detect minimum inhibitory concentration (MIC), which can be done only in a reference laboratory. The E-test<sup>84</sup> is a good alternative method and owing to its simplicity and good reproducibility is well-suited for routine use in developing countries.

### Serological Tests

Dot immunobinding and EIA procedures have been reported to have utility in epidemiological studies but not for the clinical diagnosis of patients with chancroid.<sup>85</sup>

## GENITAL HERPES

Genital herpes (GH), a prominent STI, is caused by the herpes simplex viruses (HSVs), large, enveloped DNA viruses consisting of two distinct serovars HSV-1 and HSV-2.<sup>86</sup> The family contains a number of other human pathogenic viruses. The HSV-1 usually causes oropharyngeal and ocular disease and HSV-2 is usually associated with genital infections, the most common cause of GH globally. However, both the serovars have been associated with various sites and the conditions are clinically indistinguishable. HSV-2 is also known to cause recurrent infections more frequently. Primary HSV infection is often asymptomatic. The infection during pregnancy may be transmitted to the newborn.<sup>87</sup> GH presenting as a genital ulcer is usually diagnosed clinically but as there are other conditions having a similar presentation, laboratory confirmation is required for accurate diagnosis, treatment, and counseling.<sup>88</sup>

## Laboratory Diagnosis

**Collection and transport of specimens:** The specimens are obtained from vesicular fluid, cervical swab, or swab from the ulcer base. The fluid of a large vesicle is collected with a sterile syringe with 26-gauge needle or capillary tube. The small vesicles or base of open lesions are swabbed vigorously with cotton

tipped swabs on a wire shaft. If vesicles are not present, the urethral meatus of men can be swabbed. In women with HSV infection of cervix/vagina, the ectocervix and the junction of ecto and endocervix are swabbed. For asymptomatic women, one swab premoistened with saline is used to rub the clitoral hood, labia minora, labia majora, perineum, and perianal region. All the specimens are placed immediately after collection into vials containing 1 ml of viral transport medium and stored at +4°C till inoculation into tissue culture. However, for storage beyond 48 hours, freezing of the specimen at –70°C is advisable.<sup>89</sup>

## Laboratory Methods

Non-culture diagnostic methods.

### Microscopy

Smears may be prepared from the base of the ulcer (Tzanck preparation) and stained by Giemsa/H&E/Papanicolaou (Pap) stain/Wright<sup>89</sup> and observed for the presence of multinucleated giant cells (Fig. 26.3) with intranuclear eosinophilic inclusion bodies surrounded by a clear halo. In the smear from ecto/endocervix stained by Pap stain, both endo and ectocervical cells may show herpes inclusion bodies. Although very rapid, inexpensive, and simple, the test is not adequately sensitive (50%) and specific (30–80%). The sensitivity depends on the quality of specimens, the staining method, and expertise of the microscopist. Cytology cannot differentiate between HSV-1 and HSV-2, or between HSV and varicella zoster virus (VZV). However, in the absence of alternative investigations, the test can be used in the diagnosis of genital ulcers.

### Detection of Antigen

**Direct Immunofluorescence (DIF)** A rapid cytospin-enhanced DIF using Chemicon HSV monoclonal antibodies is highly sensitive and more sensitive than culture. These slides contain a greater number of total cells than standard cell spots, resulting in fewer inadequate cell smears and a higher HSV detection rate.<sup>90,91</sup> The smears are stained with fluorescein-labeled monoclonal antibodies, specific to individual serovars, on two smears fixed on the same slide. Intracellular apple green fluorescence is observed in positive samples. The sensitivity is less during asymptomatic shedding. Negative results should be confirmed by a more sensitive assay.

**Fig. 26.3:** Giemsa-stained smear of a herpetic genital ulcer showing multinucleated giant cell.

**Direct Immunoperoxidase Assay (DIP)** Anti-HSV antibodies conjugated with enzyme peroxidase are added to the specimen, followed by treatment with diaminobenzidine, which reacts with peroxidase enzyme forming a reddish brown complex in the specimen where the antibody is bound to the viral antigen. Specimens from suspected HSV genital and skin lesions are tested on Hep-2 cell monolayer, examined for the presence of cytopathic effect, and also tested by DIP and DIF.<sup>91,92</sup> The test is recommended for laboratories without the facility of FM.

**EIA** A double-antibody EIA employing a polyclonal rabbit capture antiserum together with type-common and type 2-specific monoclonal antibodies as detectors is highly sensitive for identification of HSV as compared with cell culture and highly specific for typing as compared with DIF and restriction endonuclease analysis. Direct EIA (Herpcheck) alone was not sensitive enough, but in combination with culture, maximum detection is achieved.<sup>93</sup>

### DNA Investigation

**DNA Hybridization** The sensitivity and specificity of a DNA probe in comparison to standard viral isolation in tissue culture are 92% and 63%, respectively. The test is rapid and convenient, but lacks type-specific information.<sup>94</sup>

**PCR** The sensitivity of conventional PCR is much less than cell culture but specificity is very high.<sup>95</sup> Nested-PCR is an effective diagnostic and typing method for HSV with its higher sensitivity and specificity to routine viral isolation in cell culture.<sup>96</sup>

A RT-PCR is a highly reproducible, rapid (<4 hours), and labor efficient method for HSV-2 detection in genital swabs. It significantly increases HSV detection in both early (<5 days) and late (≥5 days) presentations and in both first and recurrent episodes.<sup>97</sup> An in-house RT-PCR hydrolysis probe assay for the detection of HSV from various clinical samples performs well and combined with careful clinical interpretation, the detection, differentiation, and quantification of HSV from mucocutaneous swab samples should improve.<sup>98</sup>

A M-PCR assay for detection of HSV-1 and HSV-2 DNA has higher sensitivity and improved turn around time than traditional culture of HSV in MRC-5 cells with confirmation by DIF. Subtyping may also be done by PCR.<sup>99</sup> A M-PCR-based reverse line blot (M-PCR/RLB) assay developed to detect 14 urogenital pathogens or putative pathogens, including HSV1 and HSV2, in FVU from men, is accurate, convenient, and inexpensive.<sup>100</sup>

A pol PCR is a cheaper and more easily reproducible method for typing HSV isolates as compared to the DIF test and could replace it as availability of PCR machines is now more widespread than fluorescence microscopes in a country like India.<sup>101</sup>

### Isolation

Viral culture is considered as the gold standard in laboratory diagnosis of HSV. The common cells used are the African green monkey kidney (Vero), baby hamster kidney, guinea pig embryo, human amnion cells, human diploid fibroblasts, etc. Cytopathic

effects (CPE) are usually observed as early as 18–24 hours but may take 4–6 days, depending upon the concentration of virus in the specimen. It includes the rounding of cells, which later becomes swollen and refractile and finally die and detach from the surface of the culture vessel. Various immunological methods like neutralization, DIF, and nucleic acid hybridization procedures may be used to identify the isolates when unusual CPE occurs or when the patient is asymptomatic. DIF is commonly used with fluorescein-conjugated type specific anti-HSV antisera.<sup>92,101</sup> Shell vial culture remains the test of choice for obtaining maximum diagnostic yield from the sample.<sup>102</sup>

### Serological Tests

As mentioned earlier, with any diagnostic test, the prevalence of the disease in the population is essential for interpreting the test result. During a primary episode of GH, when there is no antibody/low level of antibody in the acute sample, serology can help in diagnosis if there is a four-fold rise in titer in the repeat sample. However, less than 10% patients with recurrent episodes of the disease show a rise in antibody titer in the convalescent sera. The absence of rising titer does not exclude HSV infection. Patients with subclinical or atypical presentations cannot be identified by most HSV antibody tests. Sensitive tests like EIA for IgM detection are available for the diagnosis of acute episodes. However, IgM-specific antibody responses are not always restricted to primary infections; reactivation or reinfection may result in IgM response.

### Type-Specific Serology (TSS)

Accurate identification of individuals with GH is necessary for optimal patient management and prevention of transmission. It is also important to know the HSV type to counsel on the natural history of infection and risk of transmission. TSS assays have overcome the technical problems associated with earlier cross-reaction in HSV serological assays.<sup>103</sup>

**POC Kit HSV-2** A HSV-2 IgG-specific antibody lateral-flow immunochromatographic assay (LFIA) based on colloidal gold nanoparticles has excellent sensitivity, specificity, and concordance for both serum and whole-blood samples, compared to that of both HSV-2 EIA and IB.<sup>104</sup>

**EIA** Two commercial EIAs (Herpe-Select 2 and the Euroimmun EIA) use purified glycoprotein gG-2 specifically for detection of HSV-2-specific IgG antibodies. The concordance of positive and negative results between the two is 100%.<sup>105</sup> Commercial EIAs compare well with the results obtained by monoclonal antibody-blocking EIA (MAb-EIA). The Kalon EIA has a higher specificity than the Herpe-Select EIA.<sup>106</sup>

**Express Assay (EA)** This new POC test provides results similar to EIA for the identification of HSV-2 type-specific antibody among pregnant women and in conjunction with confirmatory EIA testing improves the PPV of HSV-2 serodiagnosis.<sup>107</sup>

PCR has, by far, the greatest sensitivity and should be the test of choice for symptomatic cases. HSV-2-TSS is indicated

for patients with genital lesions in whom antigen detection, culture or PCR fail to detect HSV and for patients who are asymptomatic but have a history suggestive of GH. HSV-2-TSS is further indicated for patients infected with HIV and along with HSV-1 TSS, the test may be considered as appropriate in (i) evaluating infection and/or immune status in couples discordant for GH, (ii) women who develop their first clinical episode of GH during pregnancy, (iii) asymptomatic pregnant women whose partners have a history of GH or HIV infection, and (iv) women contemplating pregnancy or considering sexual partnership with those with a history of GH. The above tests should be performed in conjunction with counseling of infected persons and their sex partners.<sup>108</sup> Clinicians need to be aware of the test limitations and should consider whether the results influence the treatment or outcome, otherwise testing is a waste of limited health resources and is not indicated.<sup>109</sup>

### GRANULOMA INGUINALE (DONOVANOSIS)

Granuloma inguinale is characterized by chronic granulomatous, beefy, erythematous, painless lesions with whitish border, involving skin, mucous membrane, and the lymphatic system of the genitalia and perianal area. It is caused by *Calymmatobacterium granulomatis* (*C. granulomatis*). The organism is a gram-negative bacterium (1.5  $\mu\text{m}$   $\times$  0.7  $\mu\text{m}$ ) and is usually found in large mononuclear cells within clear spaces or vacuoles. It is also called a Donovan body (DB), after the physician who first visualized the organism in such a lesion. The disease has recently been the subject of renewed interest after a long period of relative obscurity. *C. granulomatis* and human *Klebsiella* species are ultrastructurally, morphologically, and antigenically indistinguishable. Phylogenetic analysis confirms close similarities and *C. granulomatis* is proposed to be reclassified as *Klebsiella granulomatis* *comb nov.*<sup>110</sup>

### Laboratory Diagnosis

**Collection of tissue specimen:** The diagnosis is usually made from tissue smears. The border of the well-defined ulcer is cleaned with sterile gauze soaked in saline and wiped clean. A small piece of tissue is removed with a scalpel, a punch biopsy, forceps or the sharp end of a broken slide and kept on a clean grease free microscope slide.<sup>111</sup> Another grease-free slide is held on the piece of tissue and pressed firmly so that the tissue is crushed between the two slides.<sup>112</sup> The crushed tissue is spread on the slide and the smear so obtained is allowed to dry in air.

### Laboratory Methods

Non-culture diagnostic methods.

#### Microscopy

The smear is stained with the Leishman/Giemsa<sup>111</sup> and other Romanowsky stains for microscopy. Slow Giemsa, an overnight technique was found to have a 100% success rate in one study.<sup>113</sup> A 1 minute staining technique has been described.<sup>114</sup> The smear

is found to contain predominantly mononuclear phagocytes. DBs are observed as bluish purple coccobacilli of about 20–90  $\mu\text{m}$  diameter inside big clear to acidophilic vacuoles/capsules. The bacteria are pleomorphic with prominent polar granules and may typically be seen as “halters” or safety pins.

#### Histopathology

The organism can be demonstrated by histopathological examination of the tissue and it may be helpful in the differential diagnosis of other similar conditions. It shows an ulcer with an infiltration of plasma cells, neutrophils and histiocytes with complete absence of lymphocytes. Presence of DBs within the histiocytes in cells stained with Warthin Starry silver impregnation stain helps in the diagnosis.<sup>115</sup>

#### DNA Tests

**PCR** The first PCR assay designed to differentiate *C. granulomatis* from other *Klebsiella* species<sup>116</sup> has been successfully incorporated into a colorimetric detection system for *C. granulomatis* with two levels of specificity.<sup>117</sup>

#### Isolation

Cultivation of *C. granulomatis in vitro* was done in the past using media containing some of the growth factors contained in egg yolk.<sup>118</sup> Later, it was grown in a human monocyte co-culture system<sup>119</sup> requiring fresh monocytes from healthy donors. Successful culture of the organism onto cycloheximide-treated HEp-2 cell monolayer is now reported. The organisms appear as pleomorphic bacilli with characteristic bipolar staining and “safety pin” appearance.<sup>120</sup>

#### Serology

**Indirect Immunofluorescence (IIF):** The test for the detection of antibody in the serum shows high sensitivity and specificity.<sup>121</sup>

## Presenting with Genital Discharge

### GONORRHOEA

Gonorrhoea is one of the oldest known diseases in human beings, transmitted almost exclusively through sexual contact. The causative agent is *N. gonorrhoeae*, a gram-negative diplococcus (GNDC) with adjacent sides concave (coffee bean shaped). It is always considered as a pathogen of great clinical significance.<sup>122</sup> In men, the organism commonly produces anterior urethritis, presenting with dysuria and purulent discharge. Many other organisms like *C. trachomatis* produce a similar syndrome called non-gonococcal urethritis (NGU) and it is difficult to make an absolute distinction between the two on clinical grounds. In women, a wide range of clinical presentations is known, the most common being cervicitis. Asymptomatic infections are common. An important complication in women is pelvic inflammatory disease (PID). In neonates, ophthalmia neonatorum or neonatal

conjunctivitis is known. Epidemiological studies suggest that there is greater risk of acquiring HIV in the presence of gonorrhoea.<sup>123</sup>

## Laboratory Diagnosis

Microbiological tests are mandatory for the diagnosis in both sexes. Rapid diagnosis, using careful laboratory techniques, is important for the control of infection in the community, as the disease has got a short incubation period and high infectivity. This includes careful selection and collection of proper specimens and their immediate transport to the laboratory for culture and other techniques. The preliminary diagnosis is ideally done in the clinic with facilities for direct microscopy, and treatment can follow immediately in about 95% of men and 60% of the women.

### Collection of Specimen in Men

**Urethral swab:** The most important site for collection of a specimen in heterosexual males is the urethra. While wearing sterile gloves, the specimen is collected at least 2 hours after the patient has urinated, as voiding decreases the amount of exudate and reduces the chances of detecting the organisms. The prepuce is retracted, the tip of the meatus cleaned with normal saline and the pus is collected directly on the sterile swab if purulent discharge from the urethral meatus is present. If no discharge is seen, the urethra is gently stripped/milked towards the orifice to express the discharge. If no discharge is obtained, a sterile thin calcium alginate swab with a flexible wire shaft (intraurethral swab)/sterile bacteriological loop is inserted 2–3 cm into the urethra and rotated for 5–10 seconds to gently scrape the mucosa of the terminal part of the urethra. In case no evidence of urethritis is found on examination, but there is a history of contact, the patient is asked to hold urine overnight, urethra massaged and the discharge, if any, is collected and processed similarly.

**Urine:** First void urine (FVU) may also be a useful specimen.<sup>2</sup> The first 10–15 ml of the early morning urine is collected in a sterile plastic container with a large opening. Urine samples should be processed immediately, as it may be toxic for *N. gonorrhoeae* on standing.<sup>124</sup>

### Collection of Specimen in Women

**Endocervical swabs:** In women, usually an endocervical specimen is collected. In menopausal women or in those who have undergone hysterectomy, cervical specimens are not collected since gonococci in this age group involve the vagina, not the cervix. No antiseptics, analgesics or lubricants should be applied. A sterile vaginal speculum is inserted in the vagina and the ectocervix is inspected in ample light. The speculum can be moistened with warm water. Sterile non-cotton swabs are inserted for 2–3 cm into the endocervical canal, rotated from side to side for a few seconds to allow the absorption of the exudate and withdrawn.

**Urethral swabs:** All the precautions, as described for males, should be observed. If pus is present on the urethral meatus, it is collected with a sterile non-cotton swab; otherwise, the urethra is massaged against the symphysis pubis and the exudate is collected.

**Vaginal swab:** Using a speculum, the posterior fornix is swabbed for a few seconds. In prepubertal girls, the discharge is collected with a swab without introducing a speculum.

**Self-obtained vaginal swabs (SOVSs):** Self-collected specimens, such as urine and vaginal swabs, can be successfully used to diagnose STIs, when they are used with nucleic acid amplification assays. This eliminates the necessity for a clinician-performed pelvic examination in women for sample collection.<sup>125</sup>

### Collection of Specimen in Both Sexes

The sites swabbed in homosexual men/women are the rectum, urethra, and oropharynx.

**Rectal swab:** If recent anal intercourse has occurred, a proctoscope is inserted first, followed by a swab stick, 3 cm into the anal canal rotating it for 10 seconds to collect exudate/mucus or mucopus from the crypts just inside the anal ring.

**Pharyngeal swab:** If orogenital contact with an infected person is suspected, a specimen is collected from the tonsillar crypts and bed of pharynx.

Cotton, calcium alginate, Dacron, rayon or polyethylene terephthalate (PET) swabs with plastic or aluminium shaft, or a bacteriological loop may be used for collection of the specimen. Calcium alginate may sometimes be toxic to certain gonococcal strains.<sup>126</sup> Two swabs should always be collected, one for direct microscopy and the other for culture. Transport media should be used if the laboratory is not in the vicinity of the clinic.

**Transport of specimens:** The best results for the isolation of the organism are obtained by bedside culture, as *N. gonorrhoeae* is highly susceptible to environmental conditions. If the laboratory is not in the vicinity of the clinic, the specimen should be transported on nutritive media such as Transgrow<sup>127</sup> or Jembec<sup>128</sup> for maximum recovery. These systems consist of a selective medium, usually present in a small chamber containing CO<sub>2</sub> or a CO<sub>2</sub> generating system. The media can be inoculated directly from the patient and transported to the laboratory either before or after incubation, or after growth appears (Fig. 26.4). Specimens can also be inoculated on non-nutritive transport media like Stuarts or Amies. A newly modified Amies charcoal swab transport system<sup>129</sup> (StarSwab SP131X) is capable of maintaining the viability of *N. gonorrhoeae* for at least 24 hours and reinforces the need for adequate sampling and timely processing of specimens to maintain optimum performance. Dry swabs should not be sent as the gonococci are susceptible to drying. The isolation rate after the transport of specimens in a non-nutritive medium at room temperature (20–25°C) is approximately 100% within 6 hours and 90% within 12 hours.<sup>130</sup> After 24 hours, recovery may not be possible, especially in asymptomatic patients.

Fig. 26.4: Smear showing gram-negative diplococci.

## Laboratory Methods

Direct non-culture techniques.

### Microscopy

Microscopy of a Gram-stained smear, using purulent material expressed from the urethra, cervix, rectum or conjunctiva is an important test for the diagnosis of gonorrhoea, especially in resource poor settings. It provides an immediate diagnosis in the clinical setting. However, in homosexual men it is always better to attempt culture and further identification, as *Neisseria meningitidis* may be present in such specimens. A smear for microscopy is prepared, fixed, and stained with gram stain. Using a bright light microscope, the smear is examined with 100× objective. The Gram-stained smear of urethral discharge in a typical positive case shows a large number of characteristic kidney-shaped GNDC lying within the polymorphonuclear leukocytes (PMNL). A slide is examined for at least 2 minutes before reporting as negative. The smear is equivocal if there are only extracellular GNDC without any intracellular ones.

**Sensitivity and Specificity of Microscopy** In men with symptomatic urethritis, the sensitivity of the urethral smear is 90–95% and specificity is 95–100%. In women, sensitivity of the cervical smear is 50–70% and specificity is 95–100%.<sup>131</sup> A direct microscopic test is not recommended for pharyngeal smears. The test is not useful as a test of cure in urethral gonorrhoea. It is less reliable in the diagnosis of long-standing and asymptomatic infections.

### Direct Detection of Gonococcal Antigen

**EIA** EIA (Gonozyne)<sup>132</sup> utilizes a polyclonal antibody to detect gonococcal outer membrane protein. It has good sensitivity and specificity, compared with swab culture. Compared to swabs, urine has less sensitivity and specificity in both sexes, especially females.

### DNA Investigation

The molecular-based approaches now available are more accurate, cost-effective, and acceptable to patients. Compared with unamplified direct probe assays, nucleic acid amplification

tests (NAATs) have better detection rates for *C. trachomatis* and *N. gonorrhoeae*, and have provided clinical laboratories with advantages over traditional culture methods. These include increased sensitivity with regard to limit of detection allowing high throughput without the need for viable organisms and the ability to perform multiplex assays for the simultaneous detection of *N. gonorrhoeae* and *C. trachomatis*.<sup>133</sup> There are some limitations for its use e.g. in (i) cases of sexual abuse where 100% specificity is desirable, (ii) requests for a test-of-cure, (iii) non-genitourinary specimens, (iv) cost, (v) risk of carryover contamination, (vi) inhibition, and (vii) inability to provide antibiotic resistance data.<sup>134</sup> In addition, there are sequence-related limitations that are unique to *N. gonorrhoeae* NAATs. Overall, the *N. gonorrhoeae* species continue to present a considerable challenge for molecular diagnostics.<sup>133</sup>

- 1. DNA probe assay:** The direct probe assays are best suited for high-volume testing among high-risk groups and for settings in which NAAT is unaffordable.<sup>135</sup> Probe assay chemiluminescence enhanced test (*Gen Probe PACE* test), a non-isotopic assay for the direct detection of *N. gonorrhoeae* in urogenital specimens has been modified (*PACE-2* test *Gen-Probe*, San Diego, California). It is equivalent to the culture method in terms of sensitivity, specificity, PPV, and NPV in both symptomatic and asymptomatic women and can serve as a suitable screening and diagnostic test for gonorrhea in women.<sup>136</sup> In symptomatic men, there is excellent agreement between Gram stain and *PACE 2*.<sup>137</sup> A Combo probe 2C combining probes against *N. gonorrhoeae* and *C. trachomatis* performs very well in endocervical specimens.<sup>138</sup>
- 2. Dot blot hybridization and *in situ* hybridization with DNA probes:** On comparison with Gram staining and culture, it is a fast and sensitive method for the detection of gonococci in urethral exudate from men.<sup>139</sup>
- 3. Amplification methods:**

(i) **PCR:** The sensitivity and specificity of an in-house PCR for the detection of *N. gonorrhoeae* from urogenital samples are very high.<sup>140</sup> The Roche Cobas Amplicor M-PCR assay can simultaneously detect both *C. trachomatis* and *N. gonorrhoeae* in endocervical and urethral swabs, and urine specimens. The target sequence is known to be present in some strains of commensal *Neisseria* species, including *Neisseria cinerea* and *Neisseria subflava*, necessitating the use of a second PCR assay to confirm positive results.<sup>141</sup> Overall, there is good agreement between the confirmed PCR assay and culture. The sensitivity of this assay in urine specimens in women is too low to recommend its routine use to test for gonorrhoea.<sup>142</sup>

A sensitive and specific *RT-5-nuclease PCR assay* can be used as an accurate and rapid test.<sup>143</sup> *RT-PCR* assay is a valuable supplement to the culture technique for diagnosis of *N. gonorrhoeae*, especially for samples from extra-genital sites such as pharynx

and rectum.<sup>144</sup> In resource-limited settings, pooling of urogenital specimens to detect *C. trachomatis* and *N. gonorrhoeae* by PCR is a simple, accurate, and cost-effective procedure, compared to individual testing.<sup>145</sup>

- (ii) **Transcription-mediated assays (TMA) and Strand displacement assay (SDA):** TMA using APTIMA *C. trachomatis* (ACT) and APTIMA *N. gonorrhoeae* (AGC) identifies the respective infections in symptomatic and asymptomatic patients and is suitable for screening males using urethral swabs or urine.<sup>146</sup> However, use of SDA, for the detection of gonococcal infection in low prevalence populations is controversial because of the likelihood of FP results. There is high concordance between the above three NAATs,<sup>147</sup> which are increasingly the method of choice for the detection of *N. gonorrhoeae* and *C. trachomatis* in extra-genital sites in males having sex with males (MSM).<sup>148</sup>
- (iii) **Ligase chain reaction (LCR):** The overall performance of LCR with swabs or FVU and pharyngeal and anorectal specimens is better than that of culture for the diagnosis of genital or extra-genital gonorrhoea.<sup>149</sup> The results of Abbott LCR and Gen Probe PACE-2 compare well with culture.<sup>150</sup> Pooling of urine specimens is a cost saving technique.<sup>151</sup>
- (iv) **Nucleic acid sequence-based amplification (NASBA):** In women, using cervical and urethral specimens, the sensitivity of both microscopy and culture are very low and that of NASBA, 90.9%, compared to PCR. In men, using urethral specimens, microscopy, culture, and NASBA displayed a sensitivity of 75%, 50%, and 100%, respectively.<sup>152</sup>

### Isolation

Culture is advised in (i) the diagnosis of rectal, oral, disseminated and asymptomatic infections in both sexes, (ii) determining antimicrobial susceptibility, (iii) assessment of treatment efficacy, and (iv) medico-legal cases. The reliability of culture depends on the technique of collection, number of sites sampled, method of transportation, composition and quality of culture media, and methods of identification.

**Culture Media and Inoculation** The maximum sensitivity of culture is achieved when a non-selective culture medium like chocolate agar is used in addition to a selective medium. Selective enriched medium with a rich nutrient base supplemented with blood, either partially lysed by heat (chocolate agar) or completely lysed by saponin, is useful for the isolation. These are Modified Thayer Martin Medium (MTM),<sup>153</sup> New York City (NYC) agar,<sup>154</sup> Lysed blood agar medium or GC Lect medium.<sup>155</sup> In some geographical areas, up to 3–10% of gonococci are susceptible to 3–4 mg/L of vancomycin used in selective media; hence, supplements with reduced vancomycin (2 mg/L) or lincomycin may be used.<sup>156</sup>

The specimen swab is rolled over approximately one quarter of the surface of the plate and the inoculum is spread with a bacteriological loop over the remaining part of the plate and incubated. The inoculated plates are incubated at 35–36°C in a humid atmosphere (70% humidity) containing 3–7% CO<sub>2</sub>, which can be provided in a CO<sub>2</sub> incubator, a container with a CO<sub>2</sub> generating tablet or a candle extinction jar with a white unscented, non-toxic candle.

**Presumptive and Confirmatory Identification of Colony** The typical colonies are seen after 24–48 hours (Fig. 26.5) and can be identified presumptively by the Gram stain and oxidase test (Fig. 26.6) and differentiated from meningococci by the superoxol test and rapid carbohydrate utilization test (Fig. 26.7).<sup>157</sup> The organism is superoxol and oxidase positive and ferments glucose.

Immunological tests using monoclonal antibodies for fluorescence/co-agglutination, or tests based on enzyme systems used on primary isolation plates are highly sensitive, specific, and rapid for confirmatory identification of *N. gonorrhoeae*.<sup>158</sup> Sensitivity of the Phadebact (R) Gonococcus Test, a slide co-agglutination test, is better than the Difco FTA test for the identification of *N. gonorrhoeae* isolated from primary plates and FP results due to cross-reactions with non-pathogenic *Neisseria* are uncommon.<sup>159</sup>

**Antimicrobial Susceptibility Testing** This is not always required for providing treatment to individual patients but may be needed to monitor (i) trends in resistance and to provide basic susceptibility information to national planners, (ii) clinical efficacy of recommended treatment regime in order to provide

Fig. 26.5: Typical gonococcal colonies.

Fig. 26.6: Oxidase test on gonococcal colonies.

Fig. 26.7: Rapid carbohydrate utilization test.

information to clinicians in cases of treatment failure, and (iii) for the study of new antimicrobial agents.

Usually, the disc diffusion technique is preferred. Determination of minimum inhibitory concentration (MIC) is recommended only for the reference laboratory. The E-test (AB-Biodisk, Solna, Sweden) is an effective, simple alternative to the reference agar dilution method for direct quantification of *N. gonorrhoeae* susceptibility.<sup>160</sup>

### Antimicrobial Resistance (AMR) in *N. gonorrhoeae*

Resistance of *N. gonorrhoeae* to antibiotics, including quinolones, has increased rapidly in recent years and has reduced the options for treatment. Globally, gonorrhoea has spread widely due to the emergence of multidrug resistance, consequent to uncontrolled use of antibiotics. Now many developed countries recommend the use of third-generation cephalosporins instead of quinolones for the treatment of gonorrhoea. Gonococcal resistance to third-generation cephalosporins given orally is emerging in Japan and elsewhere.<sup>161</sup>

According to a report on the status and trends of AMR patterns of *N. gonorrhoeae*, isolated in sentinel laboratories in the Gonococcal Antimicrobial Susceptibility Programme (GASP) under SEAR of WHO,<sup>162</sup> penicillin, tetracycline and ciprofloxacin resistance rose significantly in Indian laboratories. Strains less sensitive to ceftriaxone, but resistant to spectinomycin were reported. In Sri Lanka, gonococci showed high resistance towards penicillin (96.8%). Bangladesh reported *N. gonorrhoeae* resistant to ciprofloxacin (76%), penicillin (33%), and tetracycline (50%), and with decreased susceptibility to ceftriaxone (1.5%). Spectinomycin resistance was not observed. The report stresses the necessity for continuous surveillance of AMR pattern in this region and establishing antimicrobial policy guidelines to manage this common and important STI pathogen.

A significant increasing trend of penicillin and ciprofloxacin resistance up to 2003 and 2004 was observed in a recent study from India. Tetracycline-resistant *N. gonorrhoeae* increased significantly. Only one isolate showed resistance to spectinomycin and nine had reduced susceptibility to ceftriaxone. A substantial

proportion (23.3%) of strains was multidrug resistant (MDR). The search for new effective agents needs to be initiated to respond to the emergence of resistant isolates.<sup>163</sup> Globally, a sustained and integrated effort to reduce rates of gonorrhoea and the misuse of antibiotics is required to prevent further emergence and spread of MDR strains.

### CHLAMYDIA TRACHOMATIS INFECTION

Recognized since 1970, *C. trachomatis* is among the most common bacteria associated with STIs. Serovars D-K cause genital chlamydia infections, e.g. NGU and post-gonococcal urethritis (PGU) in males, mucopurulent cervicitis and proctitis in females, and inclusion conjunctivitis in adults and neonates. It produces a variety of complications like PID and infertility in females and epididymitis and infertility in males. Serovars L1, L2, and L3 cause lymphogranuloma venereum (LGV).

*C. trachomatis*, a gram-negative bacterium, is an obligate intracellular parasite and can only grow in tissue culture. It produces intracytoplasmic, perinuclear, acidophilic inclusion bodies during its life-cycle. Other species of *Chlamydia*, like *C. pneumoniae* and *C. psittaci* (transmitted from birds to humans), cause respiratory illnesses. STIs due to *C. trachomatis* are very common in the industrialized world. Many people, especially women, are symptom free and infections are never diagnosed or reported. The infection is common among young people and is more common in heterosexuals.

### Laboratory Diagnosis

**Collection and transport of specimens:** The gold standard in the diagnosis of genital chlamydia infection prior to the advent of NAATs used to be tissue culture. The collection of specimens and use of the appropriate swab and transport media are vital to the success of tissue culture. Plastic or metal shafts are better than swabs with a wooden stick.<sup>164</sup> Cotton-tipped swabs, if used, should be tested for toxicity.<sup>165</sup> Cytobrush is an ideal device and is more efficient at the removal of cervical mucocolumnar junction cells for the culture of *C. trachomatis*.<sup>166</sup> Recently, modified sanitary napkin (wearing for 4 hours) was found to be an effective non-invasive device for self collection of specimens to detect urogenital *C. trachomatis* infection.<sup>167</sup> In patients with genital discharge, the anterior urethra and cervix are the most important sites. Sometimes, rectal mucosa and throat can be swabbed. For LGV, the specimens collected are bubo pus, rectal swabs, and biopsy material.

**Urethral swab:** A fine, flexible shafted swab is introduced 3–4 cm into the urethra and the mucosa is gently scraped by rotating for 5–10 seconds.

**Endocervical swab:** Forceps with gauze or a large cotton-tipped swab are used to remove secretions from the ectocervix. A specimen swab is inserted 2 cm into the cervical canal and gently rotated for 10 seconds scraping the endocervical

epithelial cells, concentrating on any inflamed area or where follicles are seen.

**Bubo pus:** The bubo pus may be aspirated with a syringe and needle, if necessary, after injecting sterile saline. The pus is homogenized before inoculating into tissue culture.

**Urine:** 10–15 ml of FVU should be collected in a sterile vial.

**SOVS:** Discussed earlier.

FVU is a suitable non-invasive sample type for diagnosis of urogenital *C. trachomatis* infection in men, as its chlamydia load does not differ significantly from that of urethral swabs. Given their higher organism load compared with FVU, SOVSs are the preferred non-invasive sample type for women.<sup>168</sup> First Burst is a urine collection device which collects the first 4–5 ml of FVU and yields a specimen with a six-fold higher *C. trachomatis* organism load than the regular urine cup, by quantitative PCR. This has improved the sensitivity of a rapid test for chlamydia.<sup>169</sup> A novel postal urine transport method is used in self collection based screening of *C. trachomatis*. Urine is desiccated using an anhydrous gel composed of superabsorbent polymer and buffering agent. The gel-based method is suitable for the detection of *C. trachomatis* by PCR. In addition, ease of use, effectiveness at ambient temperature and low cost makes it well-suited for population-based *C. trachomatis* screening, particularly for geographically and socially isolated individuals.<sup>170</sup>

Specimens for culture are collected in a sucrose phosphate (SP) transport medium in cryo-vials and should be sent to the laboratory within 2 hours, to be stored at  $-70^{\circ}\text{C}$ , before inoculating tissue culture. The *chlamydiae* are viable for 24 hours at  $2-8^{\circ}\text{C}$  and if the delay in inoculation is more than 24 hours, freezing at  $-70^{\circ}\text{C}$  is advisable.<sup>171</sup>

## Laboratory Methods

Direct non-culture techniques.

### Persistent Urethral Leukocytosis

More than 4 PMNL per oil immersion field (OIF) on Gram stain of urethral secretions, or persistent pyuria in an FVU, in males, indicates ongoing urethritis. In females,  $>30$  PMNL per OIF on gram-stained smears of cervical mucus is suggestive of chlamydia cervicitis.<sup>172</sup>

### Leukocyte Esterase (LE) Testing

A combination of above and LE testing of urine is sensitive in identifying chlamydia-infected individuals but the specificity is poor and this can be used as a screening test to select patients, especially males, for specific *C. trachomatis* testing.<sup>173</sup>

### Direct Microscopy

**Giemsa Staining** The value of the examination of a Giemsa-stained smear from genital specimen for detection of inclusion

bodies is limited and is not recommended for routine laboratory diagnosis as it is time-consuming and not sensitive. Cervical scrapings are difficult to read because of the presence of mucus, cell debris, bacteria, etc. in the background. However, it is a simple technique and the microscopist may be rewarded if careful examination is done. In a Giemsa-stained smear, the nucleus of the epithelial cells stains pink. The elementary bodies (EB) of *C. trachomatis* stain purple, but the perinuclear intracytoplasmic inclusions in epithelial cells containing the reticulate bodies (RB) are strongly basophilic (Fig. 26.8) and tend to stain blue. Cytoplasmic areas around the inclusion are grey.<sup>171</sup>

**Iodine Staining** The scrapings are air dried, fixed in absolute methanol and stained with Lugol's iodine. The glycogen containing mature inclusion bodies of *C. trachomatis* stain brown in smears. The method is not sensitive.

### Detection of Antigen

As culture is slow and labor intensive, non-cultural techniques without these drawbacks have come to dominate.

**DFA Test:** This is a rapid diagnostic test carried out on clinical specimens using monoclonal fluorescein-labeled anti-chlamydia antibodies against the species-specific epitope of major outer membrane protein (MOMP) or genus-specific lipopolysaccharide (LPS). For better detection, the specimen may be centrifuged on the slide.<sup>174</sup> Free EBs appear as bright apple green dots, 300 nm in diameter, with a smooth margin. (Fig. 26.9). Ideally, at least 10 EBs should be seen before making a positive diagnosis.<sup>175</sup> The method is sensitive in symptomatic patients, permits an assessment of the quality of the specimen and is good for small batches, but is expensive, requiring expertise and high-quality FM. The specificity is high when compared to culture.<sup>176</sup>

**EIA** Commercial EIA kits, following different principles, are available for the detection of chlamydia antigen (usually LPS) in clinical specimens. Appropriate collection kits containing special swab sticks and transport media, provided along with the kits, should be used for the test. The antigen is extracted from the specimen either by heating or by detergent. The specificity and sensitivity of

**Fig. 26.8:** Giemsa-stained smear of cervical scraping showing chlamydia inclusion body.

**Fig. 26.9:** Direct fluorescent antibody test—fluorescent stained elementary bodies of *Chlamydia trachomatis*.

DFA test and EIA are similar. EIA is the test of choice in many laboratories because of its simplicity. The advantages over the DFA technique are that a large number of specimens may be processed at one time and reading is more objective. In asymptomatic males, urine immunoassay screening in combination with confirmation by DFA has been used.<sup>175</sup> The sensitivity and specificity are lower than DNA-based tests.<sup>176</sup> Specificity may be increased either by confirmation using another assay like DFA,<sup>177</sup> or by using kits with confirmatory assays using blocking antibodies.<sup>178</sup>

**Rapid Assays** Commercially available rapid assays are quite expensive but give results within 30 minutes and are therefore useful in field conditions. These are as follows:

- a. **The Biostar Chlamydia OIA** (Biostar, Inc., Boulder, Colo.): It is an optical immunoassay that provides test results in less than 30 min, using a test format that allows office-based testing. Compared to all conventional assays, the sensitivity of this test is 73.8%.<sup>179</sup>
- b. **Sure cell Chlamydia test:** The test may be carried out on cervical or urethral smears, urine and ocular specimens. It detects *chlamydia* species-specific lipopolysaccharide on a membrane, utilizing immunoperoxidase technique.<sup>171</sup>
- c. **Clear view Chlamydia test.** This test utilizes a portable antigen capture technique using a membrane-based diffusion card and is done only on endocervical specimens. It consists of colored latex particles combined with monoclonal *chlamydia* antibody to detect antigen in the specimens. It is less sensitive than culture, but specificity is high.<sup>180,181</sup>
- d. **Chlamydia rapid test**<sup>182</sup>: It is based on a monoclonal antibody to *chlamydia* lipopolysaccharide coated on a test strip, using SOVS specimens in women. The test provides results in 30 minutes. Compared with PCR and SDA, it is highly specific with high NPV, but sensitivity is less than both the tests. The test is a potentially cost effective alternative to NAATs for diagnosis and may be used as a screening tool for *chlamydia* infection.

### DNA Investigation

**DNA Probe** PACE test utilizes a non-isotopic DNA probe for the detection of specific rRNA of *C. trachomatis* in endocervical and urethral specimens.<sup>183</sup> It compares very well with DFA and the best EIAs. Subsequently, PACE 2 has been found to have sensitivity and specificity as good as EIAs and culture<sup>184–186</sup> or even better than culture.<sup>187</sup> Specimens are not adversely affected by heat or extended transit time during postal transport.<sup>188</sup>

**PCR** DNA amplification assays are superior to standard immunoassays for the diagnosis of *C. trachomatis* infections in urine samples. The common cryptic plasmid is the best amplification target.<sup>189</sup> PCR is more sensitive than culture (99% vs. 78%) with a specificity above 99%.<sup>190,191</sup> The sensitivity of a commercial kit (Amplicor Roche)<sup>191,192</sup> in male urine and female cervical specimens is approximately 20% higher than culture and antigen detection methods.<sup>192</sup> It involves PCR and DNA probe hybridization followed by final detection of PCR product by EIA.

Amplicor *C. trachomatis*/*N. gonorrhoeae* M-PCR assay provides a highly sensitive, specific and robust method for the diagnosis of both *C. trachomatis* and *N. gonorrhoeae* for the early detection of both symptomatic and asymptomatic individuals<sup>140</sup> from urethral and endocervical swabs and urine. Mailed SOVS are convenient and useful for PCR testing for genital *C. trachomatis* infection.<sup>193</sup> In resource-limited settings, pooling of urogenital specimens to detect *C. trachomatis* and *N. gonorrhoeae* by PCR is a simple, accurate, and cost-effective procedure.<sup>145</sup> A new automated Abbott M-RT *C. trachomatis*/*N. gonorrhoeae* PCR assay is also available as an alternative.<sup>194</sup>

**Ligase Chain Reaction (LCR)** This extremely sensitive and specific rapid test, utilizing a single swab and requiring convenient room temperature storage and transport of specimens, is better than culture and DFA.<sup>195,196</sup> The test is highly sensitive in detection of chlamydia urethritis as well as asymptomatic infections in FVU in men.<sup>196</sup> As mentioned earlier, the pooling of urine samples in women is sensitive, specific, and cost saving.<sup>151</sup>

**Transcription-Mediated Amplification (TMA) and Hybridization Protection Assay** Gen Probe Amplified *C. trachomatis* assay (TMA) detects *C. trachomatis* ribosomal RNA (rRNA) in endocervical and urinary specimens.<sup>197</sup> Its sensitivity and specificity are similar to culture using urine and urethral and endocervical swabs.<sup>198</sup> The APTIMA TMA assay for *C. trachomatis* and *N. gonorrhoeae* has the greatest sensitivity of all the commercial NAATs carried out in non-invasive samples containing small amounts of nucleic acid. Vulvovaginal swabs appear to be the specimen of choice in women and FVU in men.<sup>199</sup>

**Strand Displacement Amplification (SDA)** PCR, SDA, and LCR show comparable high sensitivities on single dry endocervical swab specimens from female commercial sex workers for detection of both *N. gonorrhoeae* and *C. trachomatis*. Probetec ET SDA is the only NAAT showing 100% specificity for both the infections.<sup>200</sup> In contrast, according to a later study,<sup>201</sup> the specificity is excellent,

but the sensitivity of SDA is significantly lower than that of other molecular techniques.

The sensitivity for three amplified probe assays, BDProbeTec™ (BD Biosciences, Sparks, MD); Abbott LCx®, (Abbott Diagnostics, Abbott Park, IL); Roche COBAS AMPLICOR® (Roche Diagnostic Systems, Indianapolis, IN) for detection of *C. trachomatis* using swab and urine are comparable, with the exception of COBAS AMPLICOR carried out in urine specimens from females.<sup>202</sup> The specificity for all the assays are very high.

#### Q-Beta Replicase Amplified Hybridization Assay (Gen Trak Inc.):

Although the lower limit of detection of *C. trachomatis* rRNA by this novel assay and a semi-quantitative PCR is five elementary bodies, the test is comparable to PCR.<sup>203</sup>

#### Isolation in Tissue Culture

Irradiated or cycloheximide-treated McCoy cells, BHK-21, Hela-229 have been used successfully for the isolation of *C. trachomatis*.<sup>204,205</sup> Confirmation of the isolates is done either by Giemsa or iodine stains (Fig. 26.10). Fluorescein-labeled monoclonal antibodies<sup>206</sup> can rapidly confirm the presence of inclusion bodies 48 hours after incubation (Fig. 26.11). The cell culture is not 100% sensitive, therefore the gold standard for diagnosis is expanded by using multiple non-culture tests mentioned above to identify infected specimens missed by culture.<sup>207</sup>

#### Serology

Several serological tests for the detection of IgG or IgM antibodies are available commercially. However 45–65% of patients may have antibodies as a consequence of past infection and the traditional approach for the detection of four-fold rise in titer does not seem to be applicable. Detection of antibodies may be particularly useful for the diagnosis of upper genital tract infections, especially in cases of *C. trachomatis* associated tubal factor infertility,<sup>208</sup> as these infections may not be detected by endocervical culture. Elevated titers are detected by EIA or CF and/or micro-immunofluorescence (MIF) techniques.

Fig. 26.10: Iodine-stained inclusion body of *C. trachomatis* in McCoy cell culture.

Fig. 26.11: McCoy cells with fluorescent antibody stained *C. trachomatis* inclusions (high power). Courtesy: Aruna Mittal, New Delhi, India.

Interpretation must be done carefully. A single whole antigen inclusion test is capable of detecting antibodies to a group antigen as well as type-specific antibodies to *C. trachomatis*.

The detection of IgM antibodies may also be helpful in establishing acute chlamydia infections of the genital tract and the test is sensitive and specific.<sup>209</sup> Detection of IgG and IgM antibodies are valuable for epidemiological studies.

Serologic classification has been reorganized from 15 serovars to 10 immuno-types. Four antigenic pools or complexes of *C. trachomatis*, e.g. C, D, G, F, and K complexes are recognized. Using MIF, when a specific IgM response to a different pool of *C. trachomatis* immuno-type is observed, new infections can be detected in patients who have had previous infections with other immuno-types.<sup>210</sup>

#### Lymphogranuloma Venereum (LGV)

Serological tests using the CFT or MIF are also useful in the diagnosis of LGV. Usually a MIF titer of  $\geq 256$  and CF titer  $\geq 64$  are reported to indicate acute infection.<sup>211</sup> Recently, RT-quadruplex PCR assay capable of detecting LGV, non-LGV or mixed infections simultaneously in rectal specimens, has been developed.<sup>212</sup>

#### MYCOPLASMA SPECIES AND UREAPLASMA UREALYTICUM

Mycoplasmas are the smallest free-living organisms, widespread in nature. They are prokaryotes but lack a cell wall. However, they have a unique cell membrane that contains sterols, which are not present in either bacteria or viruses.<sup>213</sup> Several mycoplasma species have been isolated from humans, of which *Mycoplasma hominis* (*M. hominis*), *Ureaplasma urealyticum* (*U. urealyticum*), and *Mycoplasma genitalium* (*M. genitalium*) colonize the genital tract. Although the role of *M. hominis* in the pathogenesis of genital infections is unclear, it has been associated with infections

in women such as pyelonephritis, PID, and post-partum fever with stillbirth.<sup>214</sup> *U. urealyticum* has been reported as a causal agent of acute urethral syndrome in women<sup>215</sup> and with reproductive failure. This organism may also be an etiological agent for NGU in men.<sup>216</sup> A large number of sexually active males without urethritis are asymptotically colonized with both species. *M. genitalium* behaves similarly to *C. trachomatis* and carriage of these two organisms may be independent of one another.<sup>212</sup> *M. genitalium* is known to cause non-chlamydial NGU in men and to be associated with PID, endometritis, and possibly preterm birth in women.<sup>216,217</sup> There is a strong association between *M. genitalium* and HIV infections.<sup>218</sup>

## Laboratory Diagnosis

**Collection and transport of specimens:** The specimens which may be used for the isolation of *Mycoplasma* or *Ureaplasma* from the genital tract are urethral swabs, urine (with or without massage of prostate and para urethral glands) or semen in men, and high vaginal or cervical swabs, and purulent aspirate from salpinges (in non-bacterial salpingitis cases) in women.

These are collected on rayon-tipped swabs on a thin wire, as certain wooden sticks may be toxic to *Mycoplasma*. Contact with antiseptics, analgesics or lubricants should be avoided.<sup>219</sup> The urethral and cervical swabs are collected as described for *chlamydia*. To preserve viability up to 24 hours, the swabs should be placed immediately in transport media such as (i) *Mycoplasma* broth without inhibitors, (ii) Stuart's transport medium, (iii) ordinary nutrient broth with horse serum, (iv) SP-transport medium containing 10% heat inactivated fetal calf serum without antibiotics,<sup>220</sup> (v) trypticase soyabroth with 0.5% albumin and 400 µ/ml penicillin.

If immediate plating is not possible, samples should be stored at +4°C and sent to the laboratory within 24 hours or frozen at -70°C in media containing protein. Endocervical swab specimens transported in FVU demonstrated higher sensitivity by RT-PCR than FVU specimens only and endocervical swab specimens transported in 2-SP medium, for detection of *M. genitalium* DNA.<sup>221</sup>

## Laboratory Methods

Direct non-culture techniques.

### Leukocyte Esterase (LE) in FVU and Presence of Leukocytes in Urethral and Cervical Smears

This combination has been used to screen patients prior to specific *M. genitalium* testing, but about 10% of infected individuals remain undetected.<sup>222</sup>

### DNA Investigation

**PCR** Specific and sensitive methods are needed for identification of *M. genitalium* as it is difficult to culture the organism from patient samples.<sup>223</sup> Compared to culture, a M-PCR for the

detection of *U. urealyticum*, *M. genitalium*, and *M. hominis* in a single amplification reaction is less sensitive, but has similar specificity. The test offers a rapid, sensitive, and easy method to detect genital mycoplasmas.<sup>224</sup> The increased sensitivity and shorter time requirement of PCR support its further development for the diagnosis of *U. urealyticum* infection.<sup>225</sup>

Good correlation is seen between a quantitative RT-LightCycler PCR and conventional 16S rRNA gene PCR assay for *M. genitalium* to determine the bacterial load in patients' specimens.<sup>226</sup> The RT-*M. genitalium* adhesin protein (MgPa) gene PCR is well-suited for the diagnosis of *M. genitalium*.<sup>227</sup> A M-PCR-based reverse line blot (mPCR/RLB) assay developed to detect 14 urogenital pathogens including *U. urealyticum*, *M. hominis*, and *M. genitalium* is accurate, convenient, and inexpensive for the detection of multiple potential pathogens in FVU specimens from men.<sup>100</sup>

**TMA** A newly developed research-only TMA (Gen-Probe Incorporated) compared to an in-house DNA-based PCR assay for detection of *M. genitalium* is highly specific and vaginal swab specimens are the most sensitive specimen type in women.<sup>228</sup>

## Isolation

**Culture Media and Method of Inoculation** The inoculated plates and broths are incubated under microaerophilic (95% N<sub>2</sub> + 5% CO<sub>2</sub>) or anaerobic conditions in plastic boxes or in glass jars with sealed lids with a roll of cotton wool soaked in water to maintain humidity.<sup>224</sup> For the isolation of *Mycoplasma* in samples from the lower genital tract, 10-fold dilutions of the specimen<sup>229</sup> are used to distinguish the number of organisms likely to represent an active infection (>10<sup>4</sup>–10<sup>5</sup>/ml) from those of a chronic low-level carriage. Ten-fold dilutions of swab eluate are either spread on standard *Ureaplasma* media or into biphasic media without methylene blue as well as into liquid *Ureaplasma* medium. Serial dilution also dilutes antibodies, antibiotics and other inhibitors present in the specimen. The media commonly used are PPLO broth and agar, Shepherd A-7B and New York City Agar.<sup>230</sup> SP4 medium has been used successfully for the isolation of *M. hominis*. Any color change within 24–48 hours in liquid medium due to metabolic activities may indicate growth and is sub-cultured immediately in PPLO agar.

## Colony Characteristics and their Identification

- (i) *M. hominis* colonies are about 200–300 µm and have classical fried egg appearance. These are stained with Dienes stain by placing a small block of the agar plate on a glass slide and covering the colony with the stain. A coverslip is added and examined microscopically under low power. The periphery of the colonies stains light blue and the centre, dark blue. *M. hominis* requires only 2 days forming colonies and producing alkaline color change without turbidity in medium containing arginine.
- (ii) *M. genitalium* colonies are much smaller, many times devoid of typical appearance and are very difficult to recover from culture, requiring 2–3 months of incubation.

(iii) *Ureaplasma* colonies, once called T-strain *Mycoplasma*, are extremely small (10–30  $\mu\text{m}$ ) and difficult to see with the naked eye. A stereoscopic microscope should be used for the identification of colonies. They do not have the fried egg appearance typical of *Mycoplasma* colonies. They are identified by their (i) ability to split urea, (ii) inhibition by erythromycin, and (iii) resistance to lincomycin. Urease activity of *Ureaplasma* may be detected on solid agar containing urea and manganese sulfate or calcium chloride.<sup>230</sup> The urea containing broth medium with the growth that has just changed color is sub-cultured on agar medium containing urea buffer and a sensitive ammonia indicator. Urea positive colonies are large and dark golden brown in color because of deposition of manganese dioxide.

A *Mycoplasma* Duo kit<sup>231</sup> shows a significantly higher detection rate than a conventional culture using A7 differential agar for the detection of *M. hominis* and *U. urealyticum*. Detection of the mycoplasmas is based on the specific metabolic properties of each organism to hydrolyze either arginine or urea.

**Serologic identification:** Due to the presence of several serotypes of *U. urealyticum*, serologic identification is difficult. However, simple typing techniques based on agar growth inhibitions,<sup>232</sup> have been reported. An EIA for serotyping *Ureaplasma urealyticum* strains using monoclonal antibodies has been reported.<sup>233</sup>

**Identification by DNA techniques:** The colonies may be detected by using PCR with genus specific primers and probes, or amplification of the 16S RNA gene and sequencing of the product. For PCR, a similar method of dilution as described in culture should be used.<sup>234</sup>

**Culture of *M. genitalium*:** An improvement of the Vero cell culture method in which the growth is monitored by quantitative RT-PCR has been reported. The complete isolation procedure from the initial inoculation to completion of single-colony cloning takes about 1 year.<sup>235</sup>

### Serology

Serological tests, including EIA, have been used to detect antibody levels against *M. hominis* and *M. genitalium* in women with salpingitis and post-partum fever.<sup>236</sup> In patients with NGU, an EIA employing cell lysate *Ureaplasma* antigen<sup>237</sup> could detect a *Ureaplasma* antibody response. The test is also positive in *Ureaplasma* negative subjects, 10% by IgG and 7.5% by IgM. Similarly in tubal infertility cases, antibodies to *U. urealyticum*<sup>238</sup> and *M. hominis*<sup>238,239</sup> were detected by EIA.

## VAGINITIS

### Candidiasis

Millions of women all over the world suffer from vulvovaginal candidosis (VVC), and symptomatic or asymptomatic infections are common. Clinical signs and symptoms are non-specific and clinical diagnosis is often not possible.

The most common etiological agent of VVC is *Candida albicans* (*C. albicans*) (85%), followed by *C. glabrata*, *C. tropicalis*, *C. krusei*, and other *Candida* species.<sup>240</sup> Non-*albicans* species produce VVC clinically indistinguishable from that produced by *C. albicans*.<sup>241</sup> The organisms are also found in about 7.2% of asymptomatic women as normal flora.<sup>240</sup> Colonization of *Candida* in the vagina occurs under certain conditions including normal physiological reproductive hormonal changes in women, diabetes mellitus and the use of broad-spectrum antibiotics.<sup>242</sup>

Although not a traditional STI, *Candida* may be sexually transmitted to male partners and cause balanitis, balanoposthitis, and NGU. Colonization of penis by *Candida* has been reported in approximately 20% of male partners of women with recurrent VVC.<sup>243</sup> Incidence of *C. glabrata*, *C. tropicalis*, and *C. parapsilosis* among HIV-positive patients has increased,<sup>244</sup> but VVC is not in itself a sentinel feature of HIV infection.<sup>245</sup>

Clinical features of VVC are non-specific, and the standard laboratory test to identify *Candida* organisms from a vaginal swab may take between 5 and 7 days. Simple, reliable and rapid diagnostic tests are not available and as many as half the women with VVC are misdiagnosed, resulting in over treatment with antifungal agents.<sup>246</sup> In diagnosing VVC, clinical findings, microscopic examination and vaginal culture results should be correlated.

### Laboratory Diagnosis

**Collection and transport of specimens:** Using a speculum, a vaginal swab is collected, preferably with a polyester swab, from the posterior fornix.<sup>247</sup> The skin surrounding the genitals is also rubbed. In men, the swab is moistened with saline and the glans is rubbed. The swabs should be sent to the laboratory, as soon as possible, to prevent drying. *C. albicans* can survive for 24 hours on a moist swab. However, the use of a transport medium is recommended.<sup>240</sup>

### Laboratory Methods

Direct non-culture tests.

**Microscopy** The specimen is placed on a glass slide with a drop of saline (if required), covered with a coverslip and examined under the high power (40 $\times$ ) lens. Budding cells and long pseudohyphae are the typical findings. The specimen can also be examined in 20% KOH preparation or in a Gram-stained smear (Fig. 26.12). The microscopic demonstration of budding cells and pseudomycelia is not confirmatory, but is suggestive of candidosis. Direct microscopy may be negative in 50% of the patients with culture positive symptomatic VVC.<sup>248</sup> *Candida* are found in tissues as yeast cells (small oval cells with budding).

**Antigen Detection** EIA to detect yeast mannan, with a sensitivity of 0.1 ng/ml, may be useful for diagnosis in cases of systemic candidosis.<sup>249</sup>

**Isolation** Although culture is the most sensitive method for the diagnosis of VVC, a positive culture does not necessarily indicate that the *Candida* isolated is responsible for the symptoms.

**Fig. 26.12:** Gram-stained smear of vaginal fluid showing *Candida* budding cells and pseudohyphae.

The swab is inoculated into tubes containing Sabouraud's dextrose agar (SDA) with antibiotics (chloramphenicol or gentamycin). Typical smooth, opaque, white to creamy, glistening colonies of *Candida* develop on incubating the tubes at 37°C for 48 hours.<sup>247</sup> A wet mount examination confirms the presence of yeast cells. Recently, commercial media containing chromogenic substrates were found to have better detection rates than SDA.<sup>250</sup> Use of cycloheximide prevents the growth of *Candida* species other than *C. albicans*.<sup>247</sup>

**Speciation-Germ Tube Test** This is a simple, rapid, and frequently used test for the identification of *C. albicans*.<sup>242</sup> A colony of *Candida* is emulsified in 0.5 ml of bovine/horse/human serum and incubated at 37°C for 2–3 hours. *C. albicans* produces short lateral hyphal filaments or germ tubes that are not constricted below the blastoconidium (Fig. 26.13). Other yeasts either do not produce germ tubes, take a longer time to do so or produce them with constrictions. *C. albicans* may be identified by production of chlamydoconidia in cornmeal agar.<sup>247</sup> Identification of other yeasts requires extensive biochemical test systems, available commercially.<sup>247</sup> Complete speciation is desirable because of variations in pathogenicity and drug susceptibility of different species.

**Serological Tests—EIA** A new EIA (SysCan3 *Candida* Pathology ELISA Kit, Rockey Biomed Ltd., Perth, Australia) for anti-

**Fig. 26.13:** Germ tube test for confirmation of *C. albicans* colonies.

*Candida* antibodies demonstrated a sensitivity of 78% and a specificity of 90%, compared to vaginal cultures in sexually active females infected with VVC. The semi-quantitative nature of the test may also allow monitoring of the progression of VVC.<sup>246</sup>

There is a need for a rapid, inexpensive, reliable, POC test to increase the diagnostic accuracy for successful treatment of genital candidosis. Ongoing concerns in management of VVC include vaginal acquisition of non-*albicans Candida* species and the development of antimycotic drug resistance in *C. albicans* vaginal isolates.<sup>245</sup>

## Trichomoniasis

Trichomonal vaginitis is a common parasitic STI caused by a protozoa, *Trichomonas vaginalis* (*T. vaginalis*).<sup>251</sup> The discharge is greenish grey and foul smelling. It remains asymptomatic in 50% of infected women but can cause vaginitis, cervicitis, preterm labor, urethritis, and prostatitis.<sup>252</sup> The infections in men are characterized as NGU, epididymitis, balanoposthitis, urethral stricture and infertility,<sup>253</sup> but most have a sub-clinical infection.<sup>251</sup> Vaginal trichomoniasis has been associated with HIV acquisition.<sup>254</sup>

## Laboratory Diagnosis

**Collection of specimen:** Under speculum examination, using a sterile swab or bacteriological loop, the sample is collected from the posterior vaginal fornix. In case of delay in reaching the laboratory, the specimen may be placed in transport media, e.g. Whittington medium/Kupferberg medium, in which the trichomonads survive for 24 hours. In men, the urethra is sampled with a cotton-wool swab or preferably a polyester swab. Centrifuged urine deposit is also a good specimen for the detection and isolation of *T. vaginalis*.

## Laboratory Methods

Direct non-culture tests.

**Wet Mount** This is a simple diagnostic procedure followed in the clinic. In a wet preparation, examined at 40× magnification, the protozoa can be identified by their typical jerky motility and are seen along with PMNL. *T. vaginalis* is an ovoid globular pear-shaped flagellate 12.25–15 µm long,<sup>255</sup> slightly bigger than PMNL. It has got four free anterior flagella and one extraposterior flagella attached to an undulating membrane extending along the length of the body and showing typical motility. DF microscopy can reveal the individual flagella and undulating membrane. Mixed infections with *Candida* or micro-organisms responsible for bacterial vaginosis are commonly seen. The wet mount reveals trichomonads in only 40–80% of cases<sup>256,257</sup> because of faulty specimen preparation, failure of immediate examination and presence of other microbes. Negative wet mount does not exclude the infection.

**PAP Stain/Giemsa (Fig. 26.14)** These methods have poor sensitivity and specificity and are not useful for routine laboratory diagnosis.

Fig. 26.14: Morphology of *T. vaginalis*—Giemsa stain.

**Detection of Antigen** (i) **Latex agglutination:** Taking the culture in Diamond medium as the gold standard, the latex technique carried out on vaginal discharge is more sensitive and efficient, and has a higher predictive value than the direct wet mount examination. It provides the diagnosis in approximately 3 minutes and due to its simplicity it may be carried out by the paramedical personnel in order to offer specific treatment on the same day.<sup>258</sup> (ii) **Dot-immunobinding assay (DIBA) with monoclonal antibody:** DIBA is as sensitive as the wet mount but less sensitive than culture.<sup>259</sup>

**DNA Investigation** (i) **DNA probe:** A multiplex probe assay for *T. vaginalis* and *Gardnerella vaginalis* (*G. vaginalis*), compared with wet mount and culture in Diamond's medium, is highly sensitive and specific.<sup>260</sup> (ii) **PCR:** Compared to culture, the sensitivity, and specificity of PCR, using vaginal samples, are quite good but with urine, the sensitivity is less. It is an alternative to culture<sup>260</sup> but exclusive use of urine-based detection is not appropriate in women. (iii) **PCR EIA:** In the absence of vaginal specimens and when culture is not feasible, urine-based PCR-EIA may be useful for the detection of trichomoniasis in both sexes.<sup>261,262</sup> It is highly sensitive (98%) for detection of *T. vaginalis* in male partners of women with trichomoniasis. Even with this test, reliable detection of *T. vaginalis* in males requires multiple specimens. The study emphasizes the importance of partner evaluation and treatment as most of the male partners of infected women are infected.<sup>263</sup> (iv) **RT-PCR (Fluorescence resonance energy transfer [FRET] probe chemistry):** FRET-based assays can provide rapid, accurate, and high-throughput detection of *T. vaginalis* and may prove useful for large-scale screening programmes.<sup>264</sup> (v) **TMA assay:** TMA assay and FRET PCR for *T. vaginalis*, in clinical samples from men (urine) and women (SOVS), showed high sensitivity and specificity.<sup>265,266</sup>

**Isolation** Culture of *T. vaginalis*, the gold standard test,<sup>255</sup> is more sensitive than the direct wet mount and detects the parasite from vaginal and urethral swabs, urine sediment or prostatic fluid. Culture is usually done in reference laboratories and is especially

useful when relatively few organisms are present. A variety of liquid and semi-solid media, like modified Diamond, Feinberg, Whittington, Trichosel, Hollander, and Kupferberg medium are used. Optimal *in vitro* growth occurs in moderately anaerobic conditions and consequently the organism will grow best at the depth of culture tubes filled with the medium. The growth appears usually in about 2–4 days, but should be examined till 7 days before discarding.<sup>267</sup> Studies suggest that modified Diamond's medium allows for prolific growth and is more suitable than Kupferberg medium.<sup>267</sup>

The *In pouch* TV test has a specimen transport vessel, growth chamber for incubation and a viewing chamber for microscopy. The reported shelf life is 15 months. The medium contains antibacterial and antifungal agents. After inoculation, the medium is incubated at 37°C for 24–48 hours and up to 5 days for positive growth. Compared with the other media used commonly in laboratories, the sensitivity is higher and it does not require opening for viewing.<sup>268,269</sup>

## Bacterial Vaginosis

Bacterial vaginosis (BV) is a polymicrobial condition characterized by a malodorous vaginal discharge associated with the presence of *Gardnerella vaginalis* (*G. vaginalis*), *Prevotella* sp. (formerly *Bacteroides* sp.), and other anaerobic bacteria such as *Peptostreptococcus* sp., *Porphyromonas* sp., *Mobiluncus* sp., and *M. hominis*.<sup>270</sup> The predominant microorganisms present in the healthy vagina are facultative anaerobic lactobacilli, earlier recognized as acidophilic,<sup>271</sup> but later as hydrogen peroxide producing.<sup>272</sup> *G. vaginalis* may be present in the healthy vagina without producing vaginal discharge.<sup>273</sup> Several gynecological and obstetric complications of BV in women are reported and BV was significantly associated with HIV seropositivity among a group of commercial sex workers in Thailand.<sup>274</sup>

## Diagnosis

The diagnosis is usually based on the presence of three of the four following characteristics in the absence of a sexually transmitted infection:

- (i) Homogeneous, grayish-white, thin, adherent vaginal discharge.
- (ii) Vaginal fluid pH of >4.5.
- (iii) Intensification of fishy odor from the discharge, on addition of 10% KOH.
- (iv) Presence of clue cells (usually representing at least 20% of vaginal epithelial cells) on microscopic examination of direct KOH mount.

**pH Test** The specimen collected from the lateral or posterior fornix is touched directly on the paper pH indicator strips (3.8–6.0). Alternatively, the pH paper can be touched on the speculum after it is withdrawn. The test is highly sensitive, but gives FP results if the specimen is contaminated with cervical mucus, semen, *T. vaginalis* infected sample or menstrual blood.<sup>275</sup>

**Amine Test (Sniff Test)** Women with BV complain of foul vaginal smell because anaerobic bacteria present in the vagina decarboxylate amino acids lysine to cadaverine and arginine to putrescine. These amines become volatile in the presence of potassium hydroxide (KOH) and produce the typical fishy odor. After a positive reaction, a specimen quickly becomes odorless upon standing as the amines rapidly volatilize completely. The test is least sensitive but the most specific single predictor.<sup>273,275</sup>

### Laboratory Methods

**Direct Microscopy** (i) **KOH mount:** A drop of vaginal fluid is mixed with a drop of 10% KOH on a glass slide, covered with a cover slip and examined under high power (40×) of microscope for clue cells. These are squamous epithelial cells studded with many small coccobacilli obscuring the edges, resulting in a stippled granular appearance of the cells. In most patients with BV, a mixture of normal exfoliated vaginal epithelial cells and more than 20% clue cells are seen.<sup>275</sup> (ii) **Gram-stained smear:** The examination of Gram-stained smear is superior to wet mount and reveals the characteristic morphology of the bacteria<sup>276,277</sup> and clue cells (Fig 26.15). Quantitative estimation of the type of bacteria can also be done. Normal vaginal flora consists of predominantly lactobacilli, which are thick gram-positive bacilli and are replaced by anaerobic bacteria and *G. vaginalis* in BV. Gram-stained smears on microscopic examination can be classified into four grades:

- Presence of only lactobacilli.
- Mixed flora, predominantly lactobacilli with few coccobacillary morphotypes.
- Mixed flora, predominantly *Gardnerella* like, anaerobic bacterial morphotypes and a few lactobacilli.
- Mixed flora of gram-positive, gram-negative and gram-variable coccobacilli in the absence of lactobacilli.

A scoring system based on the semi-quantitative assessment of *Lactobacillus* morphotypes, *G. vaginalis*, *Prevotella* sp. Morphotypes, and *Mobiluncus* morphotypes, detecting the shift from predominance of lactobacilli to predominance of *Gardnerella* and other anaerobic organisms has 89% sensitivity and 83% specificity for diagnosis in comparison with clinical criteria.

**Fig. 26.15:** Gram-stained smear of vaginal fluid showing "clue cells."

A score of 7–10 is considered diagnostic of BV.<sup>277</sup> This method has good inter-centre reproducibility.<sup>278</sup> The Ison Hay criteria<sup>279</sup> for diagnosis of BV may be more useful in clinical practice. Culture is not recommended.

## Others

### CONDYLOMA ACUMINATUM (GENITAL WARTS)

Genital infections due to human papilloma viruses (HPV) are becoming one of the most prevalent STIs in the United States.<sup>280</sup> HPVs are double-stranded DNA viruses. Approximately 20 HPV types are known to cause genital or anal lesions.<sup>280</sup> The most common types of genital HPVs are HPV-6, HPV-11, HPV-16, and HPV-18. HPV-16/18 is known to be associated with cervical intraepithelial neoplasia and invasive cancers.<sup>281,282</sup>

The immunological methods are not very useful for detecting the specific HPV types and the virus cannot be cultured. Specific laboratory diagnosis and typing of HPV has been possible with the advancement of molecular biological techniques, like nucleic acid hybridization, and PCR. However, laboratory diagnosis has, at present, not much application in clinical practice.

### Laboratory Diagnosis

**Collection of specimen:** Specimens used for diagnosis are biopsies from tumors and infected tissues and exfoliated epithelial cells, collected with wooden or plastic spatula.<sup>282</sup> Samples from the cervix should be collected from the junction of ecto and endocervix. Out of various genital sites, the penile shaft, glans penis/coronal sulcus, scrotal, perianal or anal samples, semen and urine should be sampled for optimal detection of HPV-DNA by PCR and genotyping.<sup>283</sup> The swab method used to obtain skin exfoliated cells is adequate for sample collection.<sup>284</sup>

Combined sensitivity for HPV-DNA is more than 70% when patients use Dacron swabs, cotton swabs, or cytobrushes to obtain their own vaginal specimens. SOVS may be an appropriate alternative for low resource settings or in patients reluctant to undergo pelvic examinations.<sup>285</sup> Biopsy specimens after collection can be divided into two parts, one part embedded in paraffin wax for antigen detection and *in situ* hybridization and the other suspended in PBS and frozen at  $-70^{\circ}\text{C}$  for DNA tests.<sup>282</sup>

### Laboratory Methods

#### Cytology

HPV infection in epithelium produces CPE, koilocytosis and other cellular irregularities which are detected by PAP smear.<sup>282,286</sup> The method is relatively insensitive to detect asymptomatic infections.

Koilocytes are large cells with an irregular hyperchromatic nucleus and a perinuclear clear ring in the dense cytoplasm. When koilocytosis is not exhibited, specific HPV antibodies, coupled with horse-radish peroxidase (HRP), may be used to stain HPV within infected tissue. An elevated number of koilocytes, > 8 per HPE, may suggest the possibility of HIV infection.<sup>286</sup> A diagnostic pathway, integrating liquid-based cytology, computer-assisted interpretation, and HPV DNA testing to screen for cervical cell changes, has potential to improve primary screening of women at risk and is cost effective.<sup>287</sup>

### Detection of Antigen

Commercial kits for the detection of HPV antigens by IF, EIA or DIP utilizing monoclonal antibodies raised against bovine papilloma viruses and labeled with fluorescein isothiocyanate, HRP or alkaline phosphatase, respectively, are available but their sensitivity and specificity are quite low.<sup>288</sup>

### DNA Tests

**Southern Blot (SB) Hybridization** This is the gold standard test for the detection of HPV DNA, utilizing radioactive or non-radioactive labeled probes.<sup>289</sup> Using penile swabs and cervical biopsy specimens, two commercial kits,<sup>290</sup> one utilizing SB and the other a viral type dot blot, are useful in differentiating positives and negatives. The second kit can also differentiate HPV types.

**Filter in situ Hybridization** It detects HPV directly in cells from cervical scrapings<sup>291</sup> and tissue sections. FP reactions have been reported.

**Dot Blot Hybridization** The test with optimum sensitivity and specificity is available for detection of HPV,<sup>292</sup> but is primarily a research tool.

**PCR** This test, amplifying specific target DNA sequences, is more sensitive than hybrid capture.<sup>293,294</sup> Biopsy tissues, genital swabs, saliva, and urine have shown positive HPV PCR. It can detect 10–100 copies of the viral genome, as compared to the conventional methods, detecting  $10^5$ – $10^6$  copies.<sup>295</sup> An in house and a commercial PCR for detection of HPV types 16 and 18 and a commercial M-PCR for HPV types 6, 11, 16, 18, and 33 were tested in paired urine and cervical samples of women with abnormal cytology. A higher urine/cervix HPV detection sensitivity in cancer and high-grade lesions suggests that urine testing may be done to detect HPV when these lesions are present.<sup>296</sup>

In a recent study, QRT-PCR had a higher detection rate for HPV-16 than conventional PCR in cervical, SOVS and urine specimens in women. The HPV viral load in all three sampling sites correlated with the severity of disease, determined by histology.<sup>297</sup>

**Genotyping** Due to the differences in the oncogenic activity of HPV, it is clinically important to accurately identify HPV types in a simple and time effective manner. A PCR-restriction fragment length polymorphism (PCR-RFLP) method allows

discrimination of individual mucosal HPV types in single/multiple infections.<sup>298</sup>

### VIRAL HEPATITIS

The diseases caused by hepatitis A, B, C, D, and E viruses are extremely common and pose a considerable disease burden in both developing and developed countries. Some of them, especially hepatitis C (HCV) and to some extent hepatitis B (HBV) produce persistent infection. In addition to blood transfusion, sexual acquisition and transmission can occur. Screening for these infections may be appropriate in some patients with STIs.

### Laboratory Techniques

The laboratory diagnosis is mainly based on serology. EIA for detection of all the important markers are available.

#### Hepatitis A

It is usually diagnosed by EIA. During the acute stage, IgM EIA is positive. The infection is not persistent.

#### Hepatitis B (HBV)

The virus has got several serological markers. The markers used to screen patients are HBsAg, which signifies current acute or chronic infection, HBeAg, indicating infectivity of the patients, and anti-HBc IgM, signifying past or present infection.<sup>299,300</sup>

**HBV Surface Antigen (HBsAg)** It is produced by HBV, protein in nature, and is the earliest indicator of acute hepatitis B infection. It frequently identifies infected people before symptoms appear and disappears from the blood during the recovery period. In extremes of age or in those patients with immunodeficiency, such as in AIDS, chronic infection with HBV may occur, and HBsAg remains positive. A positive (or reactive) result indicates an active infection but does not indicate whether the virus can be transmitted to others. A negative result indicates that a person has never been exposed to the virus or has recovered from acute hepatitis and has rid themselves of the virus (or has, at most, an occult infection).

**HBV Surface Antibody (Anti-HBs)** Its presence indicates previous exposure to HBV (but the virus has disappeared and the person cannot transmit it to others) or the person is vaccinated. The antibody also protects the body from future HBV infection.

**HBV e-Antigen (HBeAg)** It is a viral protein associated with HBV infections and is found in the blood only when the viruses are also present. It is often used as a marker of infectivity and may also be used to monitor the efficacy of HBV treatment.

**Anti-HBV Core Antibody (Anti-HBc)** It is an antibody to the HBV core antigen and is produced during and after an acute HBV infection. It is usually found in chronic HBV carriers as well as in those who have cleared the virus, and usually persists for life. Anti-HBc testing is either specific for the IgM antibody (anti-HBc, IgM), indicating acute infection or measuring total

antibody, anti-HBc, indicating past infection, either acute or chronic.

**HBV DNA** It is more sensitive than HBeAg for detecting viruses in the blood stream. It may be used to monitor antiviral therapy in patients with chronic HBV infections. A RT-PCR assay using the LightCycler system combines high sensitivity and reproducibility for HBV DNA quantitation in a high dynamic range of quantitation.<sup>301</sup> The test is much more sensitive than branched-chain DNA (b-DNA) assay for detection of HBV DNA in sera and is useful for early monitoring of HBV load in high-risk patients,<sup>302</sup> detecting HBV DNA levels as low as 100 copies/ml.<sup>303</sup>

### Hepatitis C

Hepatitis C virus (HCV) is a RNA virus which causes almost all cases of parenterally transmitted non-A, non-B viral hepatitis (NANBH). Although most infections become chronic, leading to chronic liver disease, most patients with HCV infection are asymptomatic. The predominant modes of transmission are by blood, blood products or other parenteral exposure, particularly injecting drug use. There is evidence of a small but definite risk of sexual transmission.<sup>304</sup>

Diagnostic tests for hepatitis C<sup>305</sup> are divided into the following two general categories:

- 1) serological assays that detect antibody to hepatitis C virus (anti-HCV); and
- 2) molecular assays that detect, quantify and/or characterize HCV RNA genomes.

Serological assays have been subdivided into (i) screening tests such as the anti-HCV EIA and (ii) supplemental test such as the recombinant immunoblot assay (RIBA). Three generations of anti-HCV EIAs have been developed, and each generation has resulted in an improvement in the sensitivity of detecting anti-HCV. Supplemental anti-HCV tests are designed to resolve FP testing by EIA. However, EIAs do not differentiate between acute, chronic or resolved infection. EIA-3 and RIBA-3 use antigens from the HCV core, non-structural (NS) 3, NS 4, and NS 5 genes. RIBA is a highly specific test.<sup>306</sup>

HCV ribonucleic acid (HCV RNA) tests indicate the presence of viremia, using target amplification techniques and can detect virus within 1–2 weeks of exposure. Results may not be consistent or comparable between different assays.<sup>307</sup> The test is potentially useful for confirming the diagnosis and monitoring the antiviral response to therapy. Q-PCR is the most sensitive test for determining hepatitis C viral load, whereas the b-DNA test appears to be the most precise method.<sup>308</sup>

## HUMAN CYTOMEGALOVIRUS (HCMV) INFECTION

### Laboratory Diagnosis

Testing for HCMV is usually not recommended as a part of routine STD screening because of the high rate of infection in the

community and because HCMV infection is usually asymptomatic. The tests are usually done when patients are having symptoms of suspected HCMV infection. EIA for detection of IgM and IgG antibodies against HCMV are usually used for screening.

### Summary

The continuing epidemic spread of human immunodeficiency viruses (HIV) calls for the early and appropriate management of patients with STIs and their sex partners for the effective prevention of HIV infection. Adequate management of STIs includes an early diagnosis and correct medical treatment, which is dependent on case finding through reliable laboratory procedures.

Though the syndromic approach to STD case management enables healthcare workers to successfully manage more patients with STIs, there are limitations to this approach. However, the approach can be made more specific by the judicious use of laboratory tests. Besides, tests are essential for the diagnosis of asymptomatic patients. The development of new and rapid nucleic acid amplification tests (NAATs) in the last decade and introduction of multiplexing have considerably widened the field of laboratory diagnosis of STIs. Use of non-invasive methods for collection of specimens, like vaginal tampons and first void urine and their transport have been found to be extremely useful for diagnosis, especially for the screening of asymptomatic low prevalence populations. The tests require evaluation in field situations to determine sensitivity and specificity.

The chapter has attempted to cover the conventional tests, the newer advents, especially in the horizon of NAATs and also the rapid POC tests for developing countries for diagnosis of the common STIs. Detailed information regarding the required specimens for each disease and their method of collection have also been provided. This will offer specific treatment for patients without any delay and in turn a step towards the goal to control the scourge of HIV infection.

## Rapid Tests for the Detection of Sexually Transmitted Infections

Rosanna W. Peeling

### Introduction

Most sexually transmitted infections (STIs) are asymptomatic, but undetected and untreated infections can lead to serious long-term complications and adverse outcomes for both pregnant women and their fetus or infant. Affordable curative therapy is available for the major bacterial STIs. Screening and early treatment are therefore critical for effective patient management to prevent the development of long-term complications and to prevent onward transmission.

### Need for Rapid Tests in the Management and Control of STIs

The 2004 World Health report shows that unaffordability and inaccessibility are two major reasons why health services fail.<sup>1</sup> This situation is the reality in many countries with a high burden of STIs. For infected individuals with STI symptoms, seeking care requires traveling long distances to reach a laboratory offering STI diagnostic services, and often the services are limited or not of high quality due to limited resources.<sup>2</sup>

For countries with limited STI laboratory services, the World Health Organization (WHO) recommends the use of syndromic management where patients are treated for all the major causes of a particular syndrome.<sup>3</sup> Syndromic management of STIs works well for urethral discharge, pelvic pain, and genital ulcer disease, but evaluations of the WHO flowcharts have shown that the algorithm for vaginal discharge lacks both sensitivity and specificity for the identification of women with *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infection.<sup>4,5</sup> To increase the specificity of syndromic management of vaginal discharge, some control programs added questions about risk behaviors to the algorithm. However, this has resulted in reductions in sensitivity without necessarily increasing specificity as women are not always aware of the risk behaviors of their partners. Most women with vaginal discharge suffer from vaginal infections such as candidiasis, bacterial vaginosis, or trichomoniasis. These vaginal infections can be diagnosed with a microscope using Gram-stained smears or wet preparation of vaginal discharge.

In the absence of microscopy, presumptive treatment with metronidazole for both bacterial vaginosis and trichomoniasis is safe and inexpensive. Unfortunately, such simple rapid tests are not available for the diagnosis of genital gonococcal or chlamydial infections in women in most developing countries. There is a great need for simple, cheap, point-of-care tests for these infections in women to increase the specificity of syndromic management and reduce over-treatment of genital gonococcal and chlamydial infections.<sup>6,7</sup>

### Principles of Rapid Tests for the Detection of STIs

Historically, Gram-stained microscopy, wet prep, pH, the amine or Whiff test, and the Rapid Plasma Reagin (RPR) Venereal Diseases Research Laboratory (VDRL) tests can provide rapid diagnostic results to guide treatment of some bacterial STIs (Table 27.1). However, tests that depend on a source of electricity to operate equipment or require batching or an experienced technician remain of limited utility in many settings in the developing world.

### MICROSCOPY

Gram-stained urethral smear has a sensitivity of 90–95% for the detection of gonorrhea in men, but this method is at best only about 50% sensitive for endocervical smear specimens from women.<sup>8</sup> Fluorescein-conjugated monoclonal antibodies are commercially available for the detection of elementary bodies of *Chlamydia trachomatis* in endocervical smears and the result can be available in less than an hour. This method has a sensitivity of 80–85% and specificity of 99% but requires a skilled and experienced microscopist as the reading is highly subjective.<sup>9</sup>

Dark-field microscopy is used for the detection of motile treponemes from wet preparations of genital ulcer material in primary syphilis. This technique has a moderate sensitivity but requires a skilled microscopist. In recent years, fluorescein-conjugated antibodies against *Treponema pallidum* have become commercially available for more specific identification of the

**Table 27.1:** Rapid Tests for the Detection of STIs

Tests	STIs	Requirements	Comments
<b>Microscopy:</b> 1. Gram stain 2. Dark field 3. Direct fluorescent antibody assay 4. Wet prep (clue cells) 5. Nugent	<i>Neisseria gonorrhoeae</i> <i>Treponema pallidum</i>  <i>Trichomonas vaginalis</i> Candidiasis Bacterial vaginosis Bacterial vaginosis	Electricity	Sensitivity 95% for men but <50% for women
<b>pH</b>	Bacterial vaginosis	None	
<b>Amine (KOH)</b>	Bacterial vaginosis		
<b>Flocculation:</b> 1. RPR 2. VDRL	Syphilis	Electricity to run centrifuge and rotator -microscope	Result not often given the same day because of batching
<b>Immuochromatography strips:</b>	<i>Neisseria gonorrhoeae</i> <i>Chlamydia trachomatis</i> <i>Trichomonas vaginalis</i> Syphilis HIV Human papillomaviruses Herpes simplex viruses	None	
Enzyme detection	Bacterial vaginosis ( <i>Gardnerella spp</i> )	None	

pathogen in primary and secondary syphilis using fluorescent microscopy.

The examination of a wet preparation of vaginal discharge on a microscope slide has a sensitivity of 50–72% for the detection of *Trichomonas vaginalis* compared to nucleic acid amplified tests and is also useful for detection of candidiasis as the morphology of the fungal hyphae is distinctive.<sup>8,10</sup> The presence of clue cells in the wet preparation is suggestive of bacterial vaginosis.<sup>8</sup> Clue cells are epithelial cells of the vagina that are covered with bacteria, giving them a distinctive stippled appearance. Gram-stained smears from a vaginal swab can also be used for the diagnosis of bacterial vaginosis. The Nugent score has been developed to standardize the diagnosis of bacterial vaginosis.<sup>11</sup> It is based on the scoring of three morphological types, large Gram-positive rods of *Lactobacillus spp.*, small Gram-negative or Gram-variable coccobacilli of predominantly *Gardnerella vaginalis* morphotypes, and Gram-negative curved bacilli of predominantly *Mobiluncas spp.* A Nugent score of 7–10, associated with a decrease in *Lactobacilli spp.*, is indicative of bacterial vaginosis.

### AMINE AND pH TESTS

Bacterial vaginosis is also characterized by a fishy odor upon addition of potassium hydroxide to the vaginal discharge (the amine test) and a vaginal pH greater than 4.5. These are simple tests that can be performed easily in a physician's office.

### FLOCCULATION TESTS

The RPR and the VDRL tests are slide flocculation tests used for the diagnosis of syphilis. The tests detect antibodies to cardiolipin, which is a lipoidal antigen extracted from the beef heart. These are non-specific (also known as non-treponemal) assays as it is not known if the antibodies that react with cardiolipin are produced against some lipid component of *Treponema pallidum* or as a result of tissue injury following infection. Biological false positive cases are known to occur with the RPR and VDRL tests, leading to over-treatment. Biological false positive reactions for RPR and VDRL can occur due to pregnancy, malaria, leprosy, viral pneumonia, or immune disorders.<sup>8,12</sup>

The RPR is performed by the addition of serum to a mixture of cardiolipin and charcoal, the resulting mixture is shaken for 8 min. The charcoal particles trapped between the antigen–antibody reaction allow the reader to visualize a grainy pattern that indicates a positive result. The VDRL test is a slide flocculation test, in which the reaction pattern is read under a microscope. The VDRL cardiolipin antigen must be freshly constituted each day of test which limits its utility in peripheral health centers. In recent years, latex particles coated with treponemal antigens are also commercially available for the rapid detection of antibodies for the serodiagnosis of syphilis using the same principle of flocculation (Fig. 27.1).

Test cards are available with circles for six reactions for the latex particle test, 10 for RPR, and 12 wells for the VDRL slide in a single run. Batching saves time and costs but is often why results are not available on the same day to guide treatment.

**Fig. 27.1:** A rapid syphilis test using latex particles coated with treponemal antigen.

### LATERAL FLOW IMMUNOCHROMATOGRAPHIC STRIPS

In recent years, 80–85% of rapid tests are lateral flow immunochromatography test strips (ICTs) which are simple to use without any laboratory equipment, making them suitable for use outside of traditional clinic settings. They can be used for the detection of either antigen or antibody in a specimen to the corresponding antigen or antibody immobilized on a nitrocellulose strip either in a dipstick format or encased in a plastic cassette.

The composition of the immunochromatographic strip and the assay principle is illustrated in Fig. 27.2 for a syphilis test. During the assay process, the specimen, which can be serum, plasma, or whole blood, is applied to the sample pad well where it is absorbed by the sample pad and rapidly diffuses into the conjugate pad. If the specimen contains treponemal antibodies, it will react with the colloidal gold-treponemal antigen conjugate to form an antibody–colloidal gold complex. The complex will move along on the nitrocellulose membrane due to capillary action and react with the immobilized treponemal antigen on the Test line to form a colored band. The excess conjugate, or free conjugate if the sample does not contain treponemal antibodies, will migrate along the membrane to the Control line, where it will interact with immobilized anti-human antibody to form a colored band. Therefore, a positive sample will display two bands, one at the Test line and one at the Control line, while a negative sample will show only one band at the Control line within 10–15 min. It is important to note that the Control line is not a control for the syphilis test, but merely to show that the specimen has migrated successfully along the nitrocellulose strip. Hence when the test does not show either a test or a Control

line in the reaction window, the test is invalid and needs to be repeated with the same or a different specimen.

ICTs are commercially available for the detection of bacterial STIs, human immunodeficiency virus (HIV), human papillomaviruses, and herpes simplex virus.<sup>13</sup> However, rapid tests that detect antigen require multi-step specimen processing resulting in a test with 7–14 steps which cannot be easily performed in a busy clinic.

In general, these ICTs allow increased access to diagnosis of STIs as they are stable for long periods at room temperature and are simple to perform with minimal training and no or minimal equipment. However, some ICTs are not thermostable making them less useful in developing country settings.<sup>14</sup> ICTs are inherently less sensitive than laboratory-based antigen or antibody detection tests as the antigen–antibody reaction can only take place in seconds versus over 30 min to an hour in a laboratory-based test. The trade-off between sensitivity and speed of availability of result is inevitable with this simple format. False negative tests (low sensitivity) are problematic as most clinicians accept test results over clinical findings and may fail to manage these cases appropriately. False positive tests (low specificity) lead to inaccurate diagnosis, over-treatment, and possibly stigma and blame.

### Ideal Rapid Test for STIs

In the near future, a new generation of rapid tests that combine the ease and speed of rapid tests with the exquisite sensitivity and specificity of nucleic acid amplified tests will be available for the diagnosis of STI syndromes (Fig. 27.3).

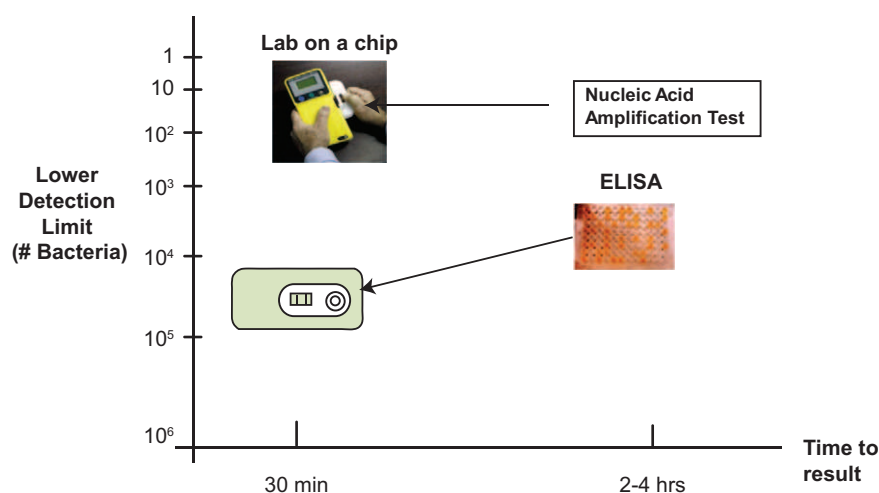

**Fig. 27.2a:** Schematic for a positive syphilis test in a lateral flow immunochromatographic format. The schematic represents four stages in the progression of a specimen containing treponemal antibodies through a lateral flow immunochromatographic strip. *Stage 1:* the treponemal antibodies represented by a yellow diamond flow from the specimen well into the sample pad. *Stage 2:* the antibodies flow through the conjugate pad and combine with colloidal gold-labeled antigen and forms a gold antigen-antibody complex. *Stage 3:* as the complex cross the Test line, it combines with the antigen immobilized on the Test line turning the Test line red. *Stage 4:* free conjugate combines with the antibody immobilized on the Control line turning it red.

If a specimen does not contain any treponemal antibodies, it would flow through the conjugate pad and the Test line without turning the line red. The free conjugate that flow through with the specimen would just turn the Control line red.

If a specimen did not migrate from the specimen well, no lines would appear in the Test line or Control line indicating an invalid assay.

**Fig. 27.2b:** Interpretation of a lateral flow assay for the detection of treponemal antibodies from a patient with syphilis.

**Fig. 27.3:** Evolution of non-culture diagnostic tests for STIs.

If rapid tests can be developed for use in health centers without traditional laboratory services, they should meet the “ASSURED” criteria developed by the WHO STD (sexually transmitted disease) Diagnostics Initiative (SDI) ([www.who.int/std\\_diagnostics](http://www.who.int/std_diagnostics))<sup>14,15</sup> (Table 27.2). The ideal test should also be a multiplex test for the detection of all the major causes of specific STI syndromes.

## Status of Current Rapid STI Tests

### SYPHILIS

Syphilis in pregnancy is a major cause of adverse pregnancy outcome in many developing countries.<sup>16–18</sup> In most countries, screening of pregnant women is a national policy but implementation rates are low because tests, such as the RPR or the VDRL slide tests, are not available in most antenatal clinics. This is because performing a non-treponemal test requires a laboratory with:

1. trained personnel;
2. refrigeration for storage of reagents;
3. electricity to run equipment: refrigerator, centrifuge to separate serum from whole blood, and a shaker to perform the serology.

Since such facilities are generally not available in rural health centers and health posts, blood or serum samples have to be transported to district or regional facilities for testing. Results

are therefore often available days or weeks after the specimens are taken.<sup>19</sup> Sometimes the specimen or the results are lost in transit. It has been estimated that approximately 30% of pregnant women are screened and treated for syphilis in sub-Saharan Africa.<sup>17</sup> A series of demonstration projects in the 1980s showed that decentralization of syphilis screening followed by immediate treatment can be effective in reducing perinatal mortality.<sup>20–23</sup> Unfortunately, decentralization has been difficult to scale up with the requirement for electricity and trained personnel.

Simple point-of-care treponemal tests, in a dipstick or cassette format, have been evaluated and shown to have sensitivities of 85–99% and specificities of 93–100% compared to laboratory-based treponemal tests.<sup>24–29</sup> These tests can be stored at room temperature and be used with whole blood obtained by finger pricks, although sensitivity can decrease by 10–20%.<sup>30</sup> More information on the performance and operational characteristics of these rapid tests can be found on the SDI website: [www.who.int/std\\_diagnostics](http://www.who.int/std_diagnostics).

A disadvantage of these rapid treponemal tests is that they cannot be used to distinguish between recent active infection and past treated infection as treponemal antibodies persist for years. However, a recent study found that treponemal tests could be more sensitive than VDRL in the detection of primary syphilis.<sup>31</sup> These tests will all be important diagnostic tools for the Global Initiative for the Elimination of Congenital Syphilis.<sup>32</sup> The advantages and disadvantages of current non-treponemal and rapid treponemal tests are summarized in Table 27.3.

In developed countries, screening and treatment of pregnant women for syphilis remain cost-effective even when the prevalence is low.<sup>33</sup> In Tanzania, where the prevalence of syphilis in pregnant women was found to be approximately 8%, it is among the most cost-effective health interventions available, at less than US\$11 per disability-adjusted life year saved.<sup>34</sup> Rapid tests cost more than current non-treponemal tests but they have been shown to be cost-effective in a number of recent studies.<sup>35–38</sup> They are particularly cost-effective when used in combination with HIV tests in Prevention of Mother to Child Transmission (PMTCT)

**Table 27.2:** The Ideal Rapid Test for STIs: ASSURED Criteria

<b>A</b>	= Affordable
<b>S</b>	= Sensitive
<b>S</b>	= Specific
<b>U</b>	= User-friendly (simple to perform in a few steps with minimal training)
<b>R</b>	= Robust and rapid (results available in less than 30 min)
<b>E</b>	= Equipment-free
<b>D</b>	= Deliverable to those who need them

**Table 27.3:** Comparison of Current Non-treponemal and Rapid Treponemal Tests

Non-treponemal tests, e.g. RPR	Rapid treponemal tests
Can be used to distinguish active from past treated infection and for test of cure	Treponemal antibodies persist for years—measure of exposure
Use serum or plasma	Use whole blood, serum, or plasma
Cannot be stored at room temperature	Test kits can be transported and stored at room temperature
Needs equipment (refrigeration of reagents, centrifuge and shaker) and trained personnel	No equipment needed
Test only takes 8 min but testing is often batched so patients are required to return for results and treatment	Results in 10–20 min and treatment given at same visit
False negative results due to prozone effect	No prozone effect

of HIV programs to prevent babies from dying of syphilis after successfully avoiding HIV.<sup>39</sup>

The greatest value of these rapid tests is in increasing the coverage of syphilis screening in rural areas of developing countries where access to laboratory services is a problem and in increasing the proportion of cases treated when return rates are low. The benefits of early detection and treatment, which prevent the serious consequences of stillbirth and congenital syphilis, outweigh the small risk of adverse drug effects associated with over-treatment.

New rapid syphilis tests that offer both non-treponemal and treponemal tests in a rapid immunochromatographic format are currently under evaluation. They allow healthcare providers to screen and confirm active syphilis infection with a single specimen at the point of care. These tools will be important for the elimination of congenital syphilis and for outreach to reduce the transmission of syphilis in high-risk populations.

## CHLAMYDIA AND GONORRHOEA

Four diagnostic companies have marketed nucleic acid amplification tests (NAATs) for the diagnosis and screening of genital chlamydial and gonococcal infections.<sup>40</sup> This has largely been driven by markets in developed countries where chlamydia screening is mandated by national STI management guidelines.<sup>41–43</sup> These tests can reliably detect 10–100 bacteria and have specificities greater than 98%.<sup>44,45</sup> The high sensitivity of NAATs makes it possible to use non-invasive specimens such as urine and self- or physician-collected vaginal swabs instead of urethral or cervical swabs. The ease of collection makes it possible to collect specimens at outreach settings or for patients to collect specimens at home and send them through the post. However, these tests are costly and are not widely available in most of the developing world where the disease burden of bacterial STIs is greatest.

More than 20 rapid tests that detect chlamydial or gonococcal antigen are commercially available worldwide. These tests are ICTs with lower limit of detection between  $10^4$  and  $10^5$  bacteria. Recent evaluations showed that although most of them have adequate specificity, they only have sensitivities of 50–70% compared to nucleic acid amplified tests for cervical swabs and 33–70% for vaginal swabs.<sup>46–48</sup> One rapid chlamydia test has been reported to have a sensitivity of more than 80% for vaginal swabs compared to urine polymerase chain reaction (PCR) in women but the test has not had any independent evaluations.<sup>49–51</sup>

Since asymptomatic individuals normally have lower bacterial load than those with symptoms, it is unclear if rapid tests of low sensitivity would be of any value for screening. A study conducted in the US showed that there might be a rapid test paradox.<sup>52</sup> In an STD clinic setting, a rapid chlamydia test with 65% sensitivity would have led to more patients being treated than an NAAT with 90% sensitivity but which requires patients to return for test results. Moreover, 3% of those infected had already developed pelvic inflammatory disease by the time they returned. Mathematical models show that the required sensitivity of a rapid test is low if there is significant STI transmission during the delay in treatment and/or few women return for treatment.<sup>53,54</sup> Hence in high-risk populations with significant possibility of transmission on a daily basis, the use of a rapid test with moderate sensitivity may be warranted in a high-prevalence setting. By giving treatment at the point-of-care and initiating partner notification, it may be possible to eliminate those with high bacterial loads from the chain of transmission within the community. This is particularly important in a high-prevalence population where patient return rates for test results and treatment are low.

## TRICHOMONIASIS

There is recent evidence that treatment of *Trichomonas vaginalis* reduces vaginal HIV shedding.<sup>55</sup> In settings where a laboratory to perform wet prep, culture, or PCR is not available, rapid tests have been developed for the detection of antigens from *Trichomonas vaginalis*. These tests have been shown to be 77–90% sensitive and 93–100% specific against culture.<sup>13,56,57</sup> However, they are more costly than the simpler tests or presumptive treatment with metronidazole.

## BACTERIAL VAGINOSIS

Bacterial vaginosis has been shown to be a factor in the acquisition of HIV and other STIs.<sup>44,45,58</sup> Women with genital discharge can be tested by pH and the amine test for the diagnosis of bacterial vaginosis if a microscope is unavailable. A number of rapid tests are available for bacterial vaginosis. They are chromogenic tests based on the detection of increased levels of microbial enzymes such as sialidases, polyamines, or trimethylamines in vaginal swab samples. They have sensitivities of 88–91% and specificity of 95% compared to the Nugent criteria.<sup>59–61</sup> One test combines a pH and the detection of proline iminopeptidase from *Gardnerella vaginalis* and has been shown

to have a sensitivity of 91% and a specificity of 62% compared to the Nugent criteria.<sup>62</sup>

### HUMAN IMMUNODEFICIENCY VIRUS

The need for rapid HIV tests to increase access to screening has driven substantial private sector investment into production of high-quality rapid HIV tests. A number of these tests have been extensively evaluated by the WHO and found to be greater than 98% sensitive and 99–100% specific compared to laboratory based tests. Details of their performance and operational characteristics are available from [www.who.int/hiv](http://www.who.int/hiv) and from the US CDC websites [www.cdc.gov/hiv/rapid\\_testing](http://www.cdc.gov/hiv/rapid_testing).

The use of these rapid tests in prenatal screening in PMTCT programs worldwide has resulted in drastic reduction in HIV transmission rates to newborns.<sup>63</sup>

The WHO recommends a three-phase approach to the use of HIV tests:

1. Evaluation of test performance in a reference laboratory using prospectively collected or archived specimens to facilitate test selection and development of testing algorithm.
2. Pilot testing algorithm at the point of service.
3. Implementation of the testing algorithm with ongoing external quality assurance and monitoring.

An assessment of this approach in 11 countries in Africa showed that in general appropriate tests were selected and the test algorithm worked well.<sup>64</sup> However, only two of 11 countries had external quality assurance programs. STD control programs should consider adopting this phased approach for the selection and use of rapid STI tests.

### HERPES SIMPLEX VIRUS TYPE 2 (HSV-2)

Rapid serologic tests for HSV-2 are commercially available.<sup>65,66</sup> They are for antibody detection and are easy to perform. Serologic tests are useful in the identification of discordant couples.

However, they are expensive and for a chronic infection such as HSV, the need for a rapid test is unclear.

### HUMAN PAPILLOMAVIRUSES (HPV)

With the introduction of two HPV vaccines, the use of HPV tests for screening has taken on a different significance.<sup>67,68</sup> A rapid test for the screening of oncogenic types in women 30 years of age or greater is commercially available. The performance of the test has not been widely evaluated but is reported to have reasonable performance against PCR.<sup>69</sup>

### Utility of Rapid STI Tests

There has been much debate whether rapid or near patient tests can improve the control of STIs.<sup>70–72</sup> The promises of rapid tests are many but so are their limitations.<sup>73</sup> Table 27.4 shows where rapid tests for STIs can make a difference.

Although the largest proportion of patients probably present to physician's offices, patients seek care at different types of clinics ranging from STI clinics, gynecology clinics, to prenatal clinics. Some present to pharmacies for treatment advice and, more recently, internet services have become more popular. Good quality rapid tests can be effectively utilized at these settings.

### PHARMACIES

Self-medication is a common practice in the developing world for many infections. This is especially true of STIs due to stigma and confidentiality issues. Many pharmacies act as surrogate clinics where the pharmacists prescribe drugs based on the self-reported symptoms of their customers. Working with pharmacists to increase their knowledge of STIs and appropriate treatment has shown good results.<sup>74,75</sup> Pharmacies can offer STI testing services or sell STI tests for home testing. Unfortunately, due to lack of regulatory oversight, many pharmacies use and sell tests with suboptimal sensitivity, giving their clients false negative results.

**Table 27.4:** Settings Where Rapid STI Tests can Make a Difference

Settings	Utility	Result
Rural or peripheral healthcare centers	Increase access to testing	<ul style="list-style-type: none"> <li>• Increased number of STIs detected and treated</li> </ul>
Health centers where syndromic management is used	<ul style="list-style-type: none"> <li>• Improve specificity of diagnosis</li> <li>• Enable partner notification and treatment</li> <li>• Reduce overuse of antibiotics</li> </ul>	<ul style="list-style-type: none"> <li>• Reduced over-treatment</li> <li>• Increased number of partners treated to prevent re-infection and onward transmission</li> </ul>
Clinics in urban centers, district and referral hospitals where laboratory services are available but STI patients need to return for results	<ul style="list-style-type: none"> <li>• Allow for immediate diagnosis and treatment</li> <li>• Prevent development of complications in the patient</li> <li>• Enable immediate partner notification and treatment</li> </ul>	<ul style="list-style-type: none"> <li>• Increased number of babies saved from still birth and congenital syphilis</li> <li>• Increased number of complications, such as cases of pelvic inflammatory disease, averted</li> <li>• Increased number of partners treated to prevent re-infection</li> </ul>
Outbreak investigation, surveillance	<ul style="list-style-type: none"> <li>• Facilitate rapid situation analysis</li> <li>• Utility in outreach and outbreak investigations</li> </ul>	<ul style="list-style-type: none"> <li>• Disease trends available for rational design of control programs</li> <li>• Increased efficacy of control and prevention programs</li> </ul>

These infected individuals may develop long-term complications and continue to transmit infection within their community.

### INTERNET SERVICES

In recent years, the internet has offered opportunities for the diagnosis of STIs.<sup>76–79</sup> There are many websites offering STI testing services or rapid test kits for home testing. These services cater to those who wish for confidentiality and to avoid stigma. Public health programs have made use of the internet to reach young people and offer excellent STI services.<sup>80–82</sup> However, most internet services and tests sold are of dubious quality as they are not subject to any regulation.<sup>83</sup>

### VENUE-BASED TESTING

Studies have shown that venue-based screening of high-risk individuals for STIs can be effective.<sup>84,85</sup> Since high-risk individuals often do not have good health seeking behavior, rapid tests offer an advantage in that testing and treatment can be offered at venues frequented by them.

## Integrated Approach for Screening of HIV and STIs

STIs have been shown to play a role in increasing the risk of HIV transmission.<sup>86</sup> Hence, opportunities for integration of STI and HIV screening at all levels of healthcare must not be missed. Individuals who test positive for one STI should immediately be offered screening for other STIs including HIV. This approach gives at risk populations a single point of access to information and services. For program managers, integrated services are more cost-effective than if the training and quality assurance of testing were provided independently.<sup>87–92</sup> In particular, rapid syphilis screening can be integrated into rapid HIV testing for PMTCT programs to avoid the tragedy of babies avoiding HIV but dying of syphilis.<sup>39</sup> Since funding for most programs are vertical, synergies between programs such as those between HIV, STIs, and reproductive health are often lost.<sup>93</sup>

## Challenges of Using Rapid Tests for STIs

If rapid tests can make a difference, and many rapid tests for STIs are currently commercially available, why are not they used more widely? The challenges faced by policy makers and control program managers are many, and they include the following.

### COSTS

Rapid tests are in most cases more expensive than laboratory tests as they are single-use tests. Laboratory tests are often batched which saves on costs and hands-on time. Decentralization of testing at different levels of the healthcare system can also require additional resources.

### LACK OF REGULATORY OVERSIGHT

In most countries in the developing world, regulatory oversight is limited or non-existent for *in vitro* diagnostics for infectious diseases, other than those used for blood banking.<sup>94,95</sup> The quality of laboratory-based tests is often better regulated through the institution of quality management systems. But this is not the case with rapid tests. As a result, many poor quality rapid tests are sold cheaply. They are bought and used without evidence of effectiveness. Companies with good quality tests will find it difficult to compete in a market that is flooded with these cheap poor quality tests.

### QUALITY CONTROL AND QUALITY ASSURANCE

With the increased access to testing and screening for STIs, it is important to ensure that the quality of the tests and the testing is maintained when tests are stored for long periods in conditions of high heat or humidity. The role of the tertiary and district level laboratories is critical in assuring the proficiency of the health workers performing rapid tests. A system of quality assurance needs to be developed and put into place as rapid tests are introduced.

## Integration into a Healthcare System

Even where there is political commitment and resources are available, there are often operational and administrative difficulties associated with the delivery of health services. In the developing world, staff shortages, lack of proper training and supervision, and frequent breakdown in the supplies of tests and medicines happen in spite of increased efforts at capacity building.<sup>96,97</sup> This means good leadership, well-trained staff, good supply chain management, quality assurance programs, and surveillance that can monitor the effectiveness of the control program or specific interventions are required.

## Future Outlook

The genomes of major bacterial STIs have been sequenced.<sup>97–99</sup> Investments in diagnostics target research will lead to the discovery of novel diagnostic targets or biomarkers, which can complement recent advances in rapid detection technologies driven and funded largely through anti-bioterrorism activities. There have therefore been more advocacy and funding opportunities for the development of new diagnostic tests to improve global health.<sup>100–103</sup> Several companies have microfluidic platforms that can test for several pathogens using a single specimen and the National Institutes of Health has funded a point-of-care test consortium to develop multiplex tests for STIs (Fig. 27.3).<sup>104,105</sup>

## Conclusions

The control of curable STIs in countries with high disease burden has been hampered by the lack of accessible STI laboratory services. Rapid tests that fulfill the ASSURED criteria have the

potential to increase the specificity of syndromic management of STIs in symptomatic patients and increase access to screening of asymptomatic infection to prevent the development of long-term complications and to interrupt the chain of transmission of STIs in the population. Increased access to testing and screening will lead to more cases of STIs being treated. Increased access to screening is critical to the success of the Global Initiative to Eliminate Congenital Syphilis and will assist countries with the attainment of their Millennium Development Goals by reducing mortality of under 5 year olds, improving reproductive health and reducing the risk of HIV transmission. Rapid tests close to fulfilling the ASSURED criteria will soon be available and can be deployed to increase access to screening in settings where testing was not previously possible or where laboratory services are inconsistent and patients return rates are low. With more political commitment and technological advances made possible by the increasing number of funders and players for test development, there is much optimism for the future for point-of-care tests for STIs that can improve patient management and disease control.

### Summary

Being frequently asymptomatic many of the sexually transmitted infections go undetected, leading transmission to the partner or the foetus with subsequent serious complications. Screening and effective treatment is critical for patient management to avoid these complications and onward transmission. Therefore, there is a great need for simple, cheap, point-of-care tests for these infections, especially in women, to increase the specificity of syndromic management and reduce over treatment of genital infections.

Historically, Gram-stained microscopy, wet-prep, pH, amine and whiff test, rapid plasma reagin (RPR-VDRL) tests do provide rapid diagnosis of most bacterial STIs; however, the tests that depend on electric supply to operate equipment, or require batching or a trained technician, remain of limited utility in the developing world. New generation rapid tests for an early and accurate detection of the infections have been introduced, most of which are point-of-care and can be used in the field without the need of maintaining the cold chain as they remain stable at room temperature. They can be performed without the use of any sophisticated equipment requiring electricity and are easily interpretable with inbuilt controls for validity of assay. Such tests are available for many sexually transmitted infections like chlamydia, gonorrhoea, trichomoniasis, bacterial vaginosis, HIV-1 and 2, HSV-2, HPV, etc. and include the slide latex agglutination assay, immunochromatography using gold conjugated detection system. Furthermore, the results are readable with naked eye. The promises of rapid tests are many, but so are their limitations.

Integration of STI and HIV screening services requires to be geared up at all levels of healthcare. This approach gives at-risk populations a single point of access to information and services. The challenges faced by policy makers and control program managers are many, and include costs, lack of regulatory oversight, and quality control and quality assurance. Besides political commitment, good leadership, well-trained staff, good supply chain management, quality assurance programs, and surveillance that can monitor the effectiveness of the control program or specific interventions are required.

With the availability of increasing number of funding agencies and players for test development there is much optimism in the future for point-of-care tests for STIs that can improve patient management and disease control.

## Genital Herpes Simplex Infections

Raj Patel • Sangeetha Sundaram • Bhushan Kumar

### Introduction

Herpes simplex virus (HSV) is the most common cause of infection related genital ulceration worldwide. The last four decades have seen an increase in prevalence in genital herpes infection in many population groups. The morbidity of the illness, high recurrence rates, and complications such as neonatal herpes present a challenge to both patients and physicians. More recently, the epidemiological interactions between HSV and HIV have resulted in renewed interest in the hope that stronger control of HSV may help limit the escalating HIV epidemic.

**Origin:** The word herpes (from the Greek, “to creep”) has been used in medicine for over 25 centuries. Cold sores (herpes febrilis) were described by the Roman physician Herodotus in 100 AD. John Astruc, physician to the king of France, first described genital herpes in 1736.<sup>1</sup>

### Biology

#### MORPHOLOGY

The HSV is a member of Herpes viridae family. It is a large DNA virus family that contains centrally located linear, double stranded DNA. At least eight members of the group are known to infect humans (Table 28.1).<sup>2,3</sup> Depending on the genomic and biological behavior, these human herpes viruses are divided into three subgroups (Table 28.1). The  $\alpha$ -herpes viruses replicate rapidly and infect a wide range of cells in cell culture. They are neurotropic in nature. The  $\beta$ -herpes viruses replicate slowly and enlarge infected cells. They infect a selective cell population in cell culture. The  $\gamma$ -herpes viruses also replicate relatively slowly and are lymphotropic in nature.

All herpes viruses are morphologically similar. They consist of four elements: (i) an electron-opaque core, (ii) an icosahedral capsid surrounding the core, (iii) an amorphous tegument containing a number of viral encoded proteins, surrounding the capsid, and (iv) an outer envelope exhibiting glycoprotein spikes on its surface (Fig. 28.1). The overall diameter of HSV is about 160 nm. The genome of HSV is a linear, double-stranded DNA

**Table 28.1:** Classification of Eight Known Human Herpes Viruses

I. Alpha herpes viruses:
(a) HSV-1
(b) HSV-2
(c) Varicella-zoster
II. Beta herpes viruses:
(a) Cytomegalovirus
(b) Human herpesvirus-6
(c) Human herpesvirus-7
III. Gamma herpes viruses:
(a) Epstein–Barr virus
(b) Kaposi sarcoma-associated herpes virus (KSHV) or Human herpes virus-8

molecule (molecular weight about  $100 \times 10^6$ ) that encodes about 80 gene products. The DNA of HSV-1 and HSV-2 are largely collinear, with reasonable, but not identical, matching of base pairs—approximately 50% of the DNA is identical.

The capsid is a protein structure, which consists of 162 capsomeres. The capsid is surrounded by a tightly adherent membrane, the tegument. The capsid and tegument are surrounded

**Fig. 28.1:** Herpes simplex virus: negative stain electron micrograph. Courtesy: CA Hart, UK.

by an envelope consisting of glycoproteins, lipids, and polyamines. The exact function of all the glycoproteins is not completely understood. The glycoproteins mediate attachment of the virus to the host cell and elicit immunological host responses to the virus. Out of the 11 glycoproteins (designated as *gB*, *gC*, *gD*, *gE*, *gG*, *gH*, *gL*, *gK*, *gL*, and *gM*), *gB* and *gC* are heparin binding glycoproteins. Some are essential for cell infection (*gB*, *gD*, *gH*, *gK*, and *gL*) while others extend the pathogenicity of the virus. Consequently, *gD*, *gB* or *gH* have become the principal targets for vaccine development. The virus attaches to the cell surface receptor (heparin sulfate) by the virion envelope, this then fuses with the cellular plasma membrane and allows the de-enveloped capsid to be transported to the nuclear pores. DNA is released into the nucleus of the cell, where a prepackaged transactivator of transcription, *VPI6*, present in the tegument, initiates the transcription of a cascade of three sets of genes. The immediate early (IE) or alpha genes initiate the replication and then activate the next set of genes, the delayed-early or beta genes. The beta genes produce enzymes necessary for viral replication, such as HSV thymidine kinase and DNA polymerase. The onset of expression of beta genes coincides with both the decline in the rate of expression of alpha genes and an irreversible shut off of the host cellular macromolecular protein synthesis (causing cell death). Gamma genes are the last to be expressed and code for structural proteins.

Assembly of the herpes virus nucleocapsids begins in the nucleus. The nucleocapsids then acquire the envelope as they bud through the inner lamella of the nuclear membrane. The enveloped particles are then transported through the cytoplasm to the plasma membrane by membrane-bound vesicles and the Golgi apparatus. The release of progeny virions occurs at the plasma membrane. The replicative efficiency of HSV is poor, as the ratio of infectious to incomplete virions is low. Productive herpes virus infection to the host cell is fatal. It also induces cell–cell fusion (polykaryocytosis), which may function as an alternative method for viral spread from one cell to another and could facilitate evasion of host immune responses.

## LATENCY

Latency is a common property of all the herpes viruses, which enables them to persist for the entire lifetime of their natural host. During latency, the viral genome is maintained in the host cell nucleus with expression of only a limited subset of viral genes. The only site of latency for HSV is the sensory ganglia of nerves innervating the initial site of infection or those subsequently inoculated. Following infection, cell-mediated immunity clears actively replicating virus from the body. Some virus, which is not cleared, remains in a virtually inactive state within neuronal tissue. This latent virus is maintained for life as extrachromosomal genetic elements (episomes) and may reactivate at any time. During latency there is a low level of DNA transcription and small amounts of viral RNA can be detected in the neuronal tissue—all of which appear to be derived from a single area

of the genome. These latency associated transcripts (LATs) are unique to HSV type and are not required for the maintenance of latency. They do have an important role in reactivation and in this they appear to act as “environmental thermometers.” Anatomical site-specific patterns of recurrence are mediated by the LATs region of the genome.

## HOST IMMUNE RESPONSE

Both innate and adaptive cell-mediated immunity are critical for limiting the spread of HSV infection and controlling viral replication.<sup>4–6</sup> Cell-mediated immunity against HSV infected cells involves NK cells, activated T cells, and macrophages. Cytokines released by lymphocytes may have direct antiviral activity or may regulate other components of the host immune response. Cytotoxic T-lymphocytes are important in the resolution of cutaneous lesions. The cellular immune response is the main factor in determining both the severity and the rate of recurrence of HSV. Both CD8+ and CD4+ lymphocyte subsets have a role in mediating protection against HSV.<sup>7</sup> Neutralizing and antibody-dependent cellular cytotoxic antibodies appear 2–6 weeks after infection and persist lifelong. Humoral immunity does not prevent recurrences or exogenous reinfections, although the thresholds for infection are raised. Antibodies acquired transplacentally are not totally protective against vertical or neonatal HSV infection. HSV recurrence is not a consequence of low antibody titer; high titers of antibodies have been shown in some studies to correlate with both a high frequency and severity of recurrent disease in adults.<sup>8,9</sup>

## REACTIVATION

The reactivation process, in many instances, has been found to be prostaglandin associated. Trauma, such as UV radiation, tape stripping of the skin, and application of retinoic acid cause reactivation in experimental models. These stimuli are associated with a local elevation of E and F class prostaglandins. Prostaglandins are rapidly synthesized in plasma membranes in response to tissue injury and are released into the extracellular space to act on target tissues. PGE<sub>2</sub> elevates cyclic AMP in target cells. Recurrences may be spontaneous or precipitated by physical or emotional stress, fever, UV light, cold, heat, food allergy, fatigue, concurrent infection, tissue damage or immunosuppression. A putative mechanism for this may be that these factors release first-order messengers, like prostaglandins, locally, or epinephrine or other “stress” hormones, systemically. These in turn elevate levels of intracellular second messengers like cAMP, which reactivate the HSV.<sup>10</sup>

## HSV AND CARCINOGENESIS

HSV DNA has been shown to induce point mutations, gene rearrangements, and gene amplifications in cells. It can also switch on exogenous DNA in cells, such as those from latent type C retrovirus and HIV, and it may switch on genes that are

not normally expressed. Despite its transforming ability, HSV alone will not induce cancer in intact animals. In one *in vitro* study, insertion of the transforming region of HSV-1 into human oral keratinocytes did not induce a malignant phenotype. In conclusion, HSV is not a primary carcinogen but can facilitate a carcinogenic process.

## Epidemiology

HSV infections are endemic throughout the world. Changing behavioral patterns particularly since the emergence of the HIV epidemic have resulted in significant alterations in the patterns of STI epidemics. Much is known about the extent of HSV infection in the developed world and Africa but there is a relative paucity of population-based studies conducted in Asian countries. In Asian countries, increased condom use and reduction in sexual contact with sex workers are responsible for reduced prevalence of many bacterial STDs.<sup>11</sup> This has resulted in a shift from syphilis and chancroid to genital herpes as the dominant cause of genital ulcer disease. Reported HSV-2 prevalence in India varies between 1.0% and 18.9% from general population-based surveys,<sup>12–16</sup> between 9.7% and 83% from STD clinics,<sup>17–19</sup> and between 2.0% and 79% from high risk group surveys.<sup>20–23</sup> A recent survey conducted in three major towns in India showed a 10.1% prevalence of HSV-2 and that prevalence increased significantly with increasing age.<sup>24</sup>

Genital herpes is the most common cause of genital ulceration in the developed world. In UK, more than 30,000 cases (2009), and in USA, more than 50,000 new cases of genital herpes are estimated to occur every year. Findings of the CDC's National Health and Nutrition Examination Survey (NHANES) estimate HSV-2 prevalence in the USA in 2005–2008 at 16.2%. This

represents only a slight decline from the last national estimate of 17% (1999–2004) indicating that HSV-2 seroprevalence rates are relatively stable. The survey also showed that HSV-2 prevalence was nearly twice as high among women (20.9%) than men (11.5%), and was more than three times higher among blacks (39.2%) than whites (12.3%). Worldwide, HSV-2 prevalence appears lower in Europe, including UK (9.7%), Eastern Europe (6–25%),<sup>25,26</sup> and Australia (16% in women, 8% in men).<sup>27,28</sup>

There is a paucity of population-based studies from developing countries. A seroepidemiological study conducted in selected populations in Brazil, Estonia, India, Morocco, and Sri Lanka showed that Brazil had the highest age-specific rates of infection for both men and women, followed by Sri Lanka for men and Estonia for women, the lowest rates being found in Estonia for men and India for women.<sup>29</sup> In all countries, HSV-2 seroprevalence increased significantly with age and adult females had higher rates of infection than adult males by age of infection. Among pregnant women prevalence has been estimated at 27% in Saudi Arabia<sup>30</sup> and 30% in the south pacific region.<sup>31</sup> Population-based studies in Africa indicate very high level of infection, for example, in South Africa, HSV-2 infection rates reach 80% in women and 40% in men by age 24.<sup>32</sup> In Latin America, infection rates range from 20% in women in Peru to 43% in female blood donors in Brazil to over 60% among men in STD clinics.<sup>33</sup> Figure 28.2 shows seroprevalence of HSV-2 in different countries. Seroprevalence of HSV-2 in selected populations is shown in Table 28.2.<sup>34–39</sup>

About 40% of newly acquired HSV-2 infections and about two-thirds of new HSV-1 infections are symptomatic. Among sexually active adults, new genital HSV infections are as common as new oropharyngeal HSV infections.<sup>40</sup> More than 85% of those identified only by HSV-2 serology will still shed virus from the genital tract over

Fig. 28.2: Seroprevalence of HSV-2 in population-based studies.

**Table 28.2:** Seroprevalence in Selected Populations (Worldwide)<sup>34–39</sup>

Patient/population group	HSV-2 seropositivity (%)
STD-clinic attendees (males)	8–65
(females)	22–55
STD-clinic attendees (both males and females)	31–83
Female prostitutes	75–96
Antenatal clinic attendees	36–53
University students	2–4
Adolescents	8–14
Infertile women	4

short periods of time<sup>19</sup>—it is generally accepted that everyone with HSV infection will shed virus in the long run. Many who acquire infection subclinically, later develop clinical recurrences.<sup>19</sup> Most cases of genital herpes are caused by HSV-2, however an increase in the incidence of genital herpes caused by HSV-1 has been reported from Europe, North America, and Australia.<sup>41–44</sup> Laboratory-based studies have identified a predominance of HSV-1 in genital lesions particularly in young people, women and men who have sex with men.<sup>45,46</sup> Many explanations have been given for more frequent occurrence of HSV-1 genital herpes. Firstly, HSV infections during childhood seem to have decreased.<sup>47,48</sup> Presence of antibody to HSV-1 correlates inversely with socio-economic status and is lowest in the developed world. Surveys in western populations have shown that 80–100% of middle-aged adults of lower socioeconomic status had been exposed to HSV-1 as compared with 30–50% of adults of higher socio-economic groups. The lower prevalence of HSV-1 immunity in children has meant that many more young adults are susceptible to HSV-1 when they become sexually active.<sup>48</sup> Secondly, greater frequency of orogenital sex as a result of “safer-sex” programs could add to this changing trend. A third possibility could be a change in viral pathogenicity.<sup>47</sup> The average annual seroincidence rates are 1.8% for HSV-1 and 1.4% for HSV-2.<sup>24,49</sup>

Pre-existing antibodies to HSV 1 often predisposes to asymptomatic genital acquisition of HSV 2 or clinically milder HSV2. Persons with prior HSV-1 infection are less likely to have systemic symptoms and have a shorter duration of symptoms and signs. Prior HSV-1 infection, however, does not alter the subsequent recurrence rate of genital HSV-2 disease.

HSV-2 seroprevalence is affected by age (antibodies are not seen until puberty), female gender, ethnicity, lifetime number of sexual partners and history of other sexually transmitted infections (e.g., gonorrhea, syphilis, and genital warts). As such, presence of HSV-2 antibody serves as a serological marker for sexual behavior in the general population and high-risk groups.<sup>50</sup>

## Transmission

The transmission of HSV-2 is more frequent from men to women than from women to men. Couple studies have shown transmission rates between 3% and 12% per year.<sup>51–54</sup> Men are more likely

to acquire HSV-2 asymptotically than women. In one study, the risk of acquisition of HSV-2 was found to be 32% in HSV seronegative women, while only 6% or less in men. The higher rates of asymptomatic infection in men may be a factor in the higher rate of male to female (as compared with female to male) transmission of HSV-2. A recently published report indicates that bacterial vaginosis (BV) appears to enhance the risk of acquisition of genital herpes simplex infection.<sup>55</sup> An analysis of results showed those who initially had BV were nearly twice more likely to have acquired the HSV-2 infection than those without BV.<sup>55</sup>

Asymptomatic viral shedding is the primary mode of herpes virus transmission. In 50–90% of instances of transmission, the infected partner is unaware of herpes infection. Asymptomatic shedding occurs most frequently in the first year after the primary episode. In a recent study of 30 HIV negative, HSV-2 seropositive homosexual men, it was found that 53.3% of these men shed HSV-2 on 3.1% of the days.<sup>56</sup> The risk of transmission is greater with HSV-2 as compared with HSV-1 isolates, from males to females and in non-users of barrier methods of contraception.<sup>35</sup> In longitudinal couple studies the median time of the relationship before transmission occurred was 3 months and the median number of sexual encounters was 24, suggesting that HSV is relatively easy to transmit. Source partner's awareness of the infection and disclosure to the sexual partner is associated with a 50% decrease in the risk of HSV-2 transmission.<sup>57</sup> Longitudinal transmission studies demonstrate that transmission rates per act of sexual intercourse decline as a relationship matures. It is unclear why this should be but may simply be a frailty effect with those relationships most susceptible to transmission through high shedding in one partner or particular risk factors for acquisition in the other managing to transmit early leaving a population who are more resistant to transmission with time.

In most cases of neonatal HSV infections, the mothers have no history of genital disease.<sup>58</sup> Mothers who acquire primary sub-clinical infection near term and who are asymptotically shedding the virus are at high risk of transmitting the HSV virus to the neonate.<sup>16</sup> In the presence of a history of recurrent lesions in the mother, the vertical transmission rate is much lower (<5%).<sup>16</sup> The passive transfer of maternal antibodies protects to some extent against severe neonatal herpes and raises the threshold for infection.

## Pathology

The histological features of herpes simplex type 1 and type 2, varicella and herpes zoster are similar. They represent a combination of virally mediated cellular death and the associated cellular response. The earliest epidermal cell changes appear in the nuclei, in the form of peripheral clumping of chromatin and a homogenous ground glass appearance combined with ballooning of the nucleus.<sup>59</sup> The earliest cytoplasmic alteration is vacuolization. The cells lose intact plasma membranes and form multi-nucleated giant cells. Initially, these changes appear in the basal layer, but later involve the full thickness of the epidermis. Two types of degenerative changes appear leading to intraepidermal vesicle formation—ballooning degeneration and reticular degeneration. In ballooning degeneration, the affected cells swell and lose their attachment to adjacent cells resulting

**Fig. 28.3:** Histology of genital herpes showing ballooning degeneration, spongiosis, and acantholysis (H&E, × 550). *Courtesy: Uma Nahar and BD Radotra, Chandigarh, India.*

in secondary acantholysis. This is characteristic of viral infections (Fig. 28.3). The acantholytic or Tzanck cells have homogenous and intensely eosinophilic cytoplasm. In reticular degeneration, there is progressive hydropic swelling of epidermal cells, which become large and clear. These eventually rupture leading to vesicle formation. Such “spongiotic” changes are not characteristic of a viral bulla and are also seen in other diseases like allergic contact dermatitis. Eosinophilic intranuclear inclusion bodies are seen in the swollen cells. Neutrophils and lymphocytes are predominant in the infiltrate.

## Cytodiagnosis

The Tzanck smear is taken from a recent lesion. The intact roof of the vesicle is opened along one side, then folded back and the bottom gently scraped. The material is smeared onto a glass slide, allowed to air dry, and stained with May–Grunwald–Giemsa stain

for 20–25 minutes.<sup>60</sup> The cytologic picture cannot differentiate between HSV-1, HSV-2, and varicella, and is frequently unhelpful even though virus can be isolated by other more reliable methods. In all of these conditions multi-nucleated giant keratinocytes are found (see Chapter 26, “Laboratory Diagnosis of Sexually Transmitted Infections”). The cells look as if they have been inflated (ballooning degeneration). The nucleus shows some blurring of the chromatin pattern and loss of staining. Intranuclear inclusion bodies surrounded by a clear halo are characteristic of herpetic infection, but are not always easy to find on smear.

## Clinical Manifestations

HSV causes a wide variety of disorders in adults and neonates (Table 28.3).<sup>61</sup> In addition to physical illness, it may also cause psychological and psychosocial problems.<sup>61</sup> To understand the clinical manifestations of genital herpes, it is important to differentiate between the first clinical episode and recurrent episodes, because the course and natural history of these entities are different (Fig. 28.4).

**Table 28.3:** HSV Infections in Humans<sup>17</sup>

### In immunocompetent hosts:

- Orolabial herpes
- Anogenital herpes
- Ophthalmic herpes
- Aseptic meningitis, myelitis
- Other sites (e.g., herpetic whitlows affecting fingers)

### In immunocompromised hosts:

- Progressive/persistent (chronic) mucocutaneous ulcerations
- Disseminated infection
- Encephalitis
- Pneumonitis
- Colitis, esophagitis
- Hepatitis

**Fig. 28.4:** Mean duration of ulcers, pain, and viral shedding in men and women in true primary, non-primary first episode and recurrent genital herpes (M–males, F–females).

**Table 28.4:** Classification of Symptomatic Genital Herpes Depending upon Paired Serologic Results and Viral Isolation

HSV type isolated	Acute phase serology		Convalescent phase serology		Classification
	HSV-1	HSV-2	HSV-1	HSV-2	
HSV-1	–	–	+	–	Primary HSV-1
HSV-2	–	–	–	+	Primary HSV-2
HSV-1	–	+	+	+	Primary HSV-1 in previously HSV-2 infected Individuals (uncommon)
HSV-2	+	–	+	+	Primary HSV-2 in previous -1 infected individuals
HSV-1	+	– or +	+	– or +	Recurrent HSV-1
HSV-2	– or +	+	– or +	+	Recurrent HSV-2

The severity of clinical manifestations and the recurrence rate of genital herpes are influenced by both viral and host factors. The first clinical episode can further be sub-divided into primary infection, occurring in a person without prior HSV-1 or HSV-2 antibody, or non-primary infection, occurring in a person with prior HSV-1/HSV-2 antibody (Table 28.4). The majority of HSV infections (both HSV-1 and HSV-2) are subclinical.

### PRIMARY GENITAL HERPES

Primary genital herpes is classically characterized by prolonged systemic and local symptoms. Pain, dysuria, urethral or vaginal discharge, genital and sacral paresthesia, and tender inguinal lymphadenopathy are the predominant local symptoms.<sup>62</sup> Lesions appear 3–14 days after exposure. Systemic symptoms appear early in the course of the disease, they begin after a mean incubation period of 6–8 days, peak within 4 days of onset of lesions and gradually abate over the subsequent 3–4 days. About 40% of men and 70% of women experience constitutional symptoms during primary disease. Headache, fever, myalgias, lethargy, backache, and photophobia are the most frequent complaints.

Local symptoms of itching, erythema, and pain usually precede visible lesions by 1–2 days. The first lesions typically are small, grouped, painful vesicles or pustules on an erythematous base, which break and form ulcers in 2–4 days. Initial lesions may involve an extensive area (Figs. 28.5 and 28.6) and individual lesions may coalesce to form large ulcers. Atypical features including the development of deep necrotic ulcers may also occur. New groups of lesions may appear during the second week. In the third week, crusts appear over lesions and the process of re-epithelialization begins. Crusting does not occur on mucosal surfaces and scarring from lesions is uncommon. Tender inguinal lymphadenopathy appears during the second or third week and may persist despite lesions healing. Involved inguinal and femoral lymph nodes are tender to palpation, firm, and non-fluctuant.

Isolated HSV cervicitis may be a sole manifestation of the first episode in about 8% of women,<sup>63</sup> however 88% of women with

**Fig. 28.5:** Widespread lesions on shaft of the penis of true primary genital herpes.

**Fig. 28.6:** Extensive vulval lesions of primary genital herpes.

primary genital HSV-2 infection have HSV-2 cervicitis.<sup>64</sup> HSV urethritis may occur as the only symptomatic manifestation in less than 5% of both men and women.<sup>65</sup> Urethral discharge and dysuria are present in about one third of men. The discharge is clear and mucoid. The severity of dysuria is out of proportion to the amount of discharge.<sup>66</sup> HSV viral pharyngitis (sore throat) can occur and HSV can be isolated from the throat in 11% of all the patients with HSV-2 genital disease.<sup>67</sup> The mean time from onset of lesions to complete healing is longer in women (about 20 days) than in men (16.5 days). The mean duration of viral shedding, as defined from the onset of lesions to the last positive culture is 12 days.<sup>67</sup>

### FIRST EPISODE NON-PRIMARY GENITAL HERPES

About 50% of patients, presenting with their first clinical episode of genital herpes, have pre-existing antibodies to either HSV-1 or HSV-2.<sup>15</sup> Most patients with first episode genital ulceration due to HSV-2 have serological evidence of prior HSV-1 infection<sup>68</sup>; acquisition of HSV-1 in persons with prior HSV-2 infection is rare. Neutralizing antibodies to HSV inactivate extracellular virus and interrupt the spread of HSV infection. The cellular response to HSV antigen also appears earlier in persons with non-primary genital herpes than in post-primary first episode. Those with non-primary first episode have lower frequencies of systemic symptoms, shorter durations of pain, fewer lesions, and shorter healing times compared with true primary infections. Constitutional symptoms are present in only 16% of patients, in contrast to 70% of the patients with true primary disease. Lesions are not widely distributed, they may be unilateral, and the mean surface area is only one-third of that in true primary disease. The mean number of days with pain, healing time, and viral shedding is about 4 days less than in true primary disease.<sup>67,69</sup>

### FIRST EPISODE IN HSV-2

#### Seropositive Patients

Diamond et al.<sup>70</sup> reported that 41 (8%) out of 498 patients, clinically judged to have first-episode HSV-2 of genital herpes, had serologic evidence of previously acquired HSV-2 infection. Bernstein et al.<sup>71</sup> have also reported that 75% of the persons thought to have first-episode non-primary infection (first episode HSV-2 infection in a person with serologic evidence of prior HSV-1 infection) had pre-existing HSV-2 antibodies. These studies have important implications upon patient management particularly around counseling and education around timing of actual infection and possible sources of HSV. The knowledge that their current sex partner may not be the source of their infection and that persons who transmit HSV are usually not aware that they have genital herpes may help in stabilizing a relationship weakened by the unexpected development of genital herpes in one partner.<sup>72</sup> When available, type-specific serologic testing and virus culture and typing during the first clinical episode can accurately determine, whether acquisition of infection was recent or remote.<sup>72</sup>

### RECURRENT GENITAL HERPES

Genital herpes caused by HSV-2 is recurrent in at least 90% of infected patients and 88% have at least one recurrence within 12 months of their initial episode (Fig. 28.7).<sup>67</sup> The mean rate of recurrence in HSV-2 genital infection is 0.3–0.4/month.<sup>67</sup> In genital herpes caused by HSV-1, 55% patients report recurrent episodes with a mean recurrence rate of 0.09/month.<sup>67</sup> Men have more recurrences than women, also, patients who had a prolonged primary infection (more than 34 days) had more frequent recurrences than those who healed faster. The change in recurrence rate over time is not clear. Some studies reported a reduction in recurrence rate after 18 months<sup>73</sup>; others found no consistent change in recurrence rate even after 5 years.

Recent long-term cohort studies, however, indicate that the frequency of symptomatic episodes gradually decreases by median of one recurrence per year.<sup>66</sup> Reactivation, both symptomatic and subclinical, is less frequent with genital HSV-1 infection when compared to genital HSV-2 infection. Recurrences can be triggered by emotional stress, sunlight, concurrent infections, and menstruation.

### Atypical Manifestations

It is not uncommon to see patients with genital herpes presenting with atypical features (Table 28.5). Genital herpes may be misdiagnosed as recurrent vaginitis, urinary tract infections or *Candida* infection in women and as folliculitis, condom allergy,

Fig. 28.7: Recurrent lesions of genital herpes.

Table 28.5: Some Atypical Presentations of Genital Herpes

- Vaginal discharge (unrelated to candidiasis)
- Genitourinary pain
- Non-specific vulvar erythema
- Prostatitis and lower back pain
- Itching, burning, soreness or pain over genitalia (without apparent lesions)
- Unexplained systemic symptoms, like fever, malaise, and myalgia
- Vulvar, penile or perianal fissures
- Folliculitis

and other dermatoses in men.<sup>74</sup> It is important to remember that people having circulating antibodies against HSV-1, who are newly infected with HSV-2, are less likely to present with classical signs and symptoms. As recent epidemiological data indicate HSV as the most common cause of genital ulcer disease, clinicians should evaluate all genital lesions, regardless of appearance for herpes.

### Psychological Factors in Recurrences

Stress is invoked as an important factor for precipitation of recurrences. Evidence suggests that patients with high levels of recurrences are more likely to blame stress than those with less frequent recurrences. However, the role of stress as precipitating factor has not been conclusively proven and there is a possibility that there might be a mood/cognitive elements to the prodrome in recurrent herpes, which may be misinterpreted as stress.<sup>75,76</sup> A recent prospective study has shown that single stressful events are not related to recurrences. While long-term stress (lasting more than 7 days) is related to recurrences. It has also been shown that more intense long-term stress is more closely related to an increased chance of recurrences.<sup>77,78</sup>

### Prodrome in Recurrent Genital Herpes

Many individuals with genital HSV infection are able to predict a recurrence of genital HSV through warning prodromal sensations. In one study, 59% of the subjects could reliably predict the onset of an episode on at least 75% of occasions by the presence of prodromal symptoms.<sup>79</sup> Localized prodromal symptoms usually appear in the form of mild tingling sensations up to 48 hours prior to any eruption.<sup>66</sup> Sometimes, shooting pains in the buttocks, legs or hips may appear 1–5 days prior to the episode. Rarely sacral neuralgia may occur.<sup>66</sup> The risk of viral shedding is high during prodromal symptoms, even in the absence of lesions. False prodromes (prodromal symptoms that do not progress to visible genital signs) do occur and are more frequent in those with more frequent recurrent disease.

### Factors Influencing Recurrence Rates

Animal studies shown that these might include inoculum size, severity of acquisition infection, herpes virus types (more genital recurrences with HSV-2 infection) and early antiviral treatment of a first episode. However, clinically only the viral type, primary or non-primary nature and extreme length of an acquisition episode have been associated with subsequent disease severity.

### Clinical Features of Recurrent Genital Herpes

Recurrent genital herpes is the mildest form of the disease. Only a limited number of vesicles, usually 3–5 in number, appear on the shaft of the penis/glans/prepuce of male patients. Although symptoms of recurrent genital herpes are more severe in women, objective clinical signs are relatively similar in both sexes. The disease is usually unilateral. Constitutional symptoms are seen

only in 5% of men and 12% of women.<sup>67</sup> The cervix is involved in 12% of episodes. The urethra is involved in 4% of the patients and 4% will develop extragenital lesions.<sup>80</sup> Painful genital ulcers occur more frequently in women than in men (88% vs. 67%),<sup>67</sup> which also persist for a longer duration (5.9 days vs. 3.9 days). There is considerable variability in the severity and duration of disease both among patients and in a patient between episodes. Only one-tenth the area involved in primary genital herpes is affected in recurrent disease. Viral shedding peaks by 48 hours from the onset of lesions and lasts for about 4 days. The mean time from onset to crusting is about 5 days in both men and women.<sup>66</sup> Complete re-epithelialization occurs in about 6–10 days.<sup>66</sup> Sometimes the episode can be abortive, characterized by itching, redness and edema but no vesicles, ulcers or crusts.

### GENITAL HERPES IN IMMUNOCOMPROMISED HOSTS

All the manifestations of HSV infections seen in the immunocompetent host can also be seen in immunocompromised patients, but they are usually more severe, extensive, difficult to treat and more frequent (Fig. 28.8).<sup>81</sup> In advanced immunodeficiency dissemination of HSV may also be seen. Recurrent and persistent ulcerative HSV lesions are among the most common infections among patients with AIDS.

**Fig. 28.8:** Chronic, large ulcers of genital herpes in a HIV seropositive immunosuppressed patient.

Atypical presentation of HSV infection can occur in patients with HIV infection,<sup>82–84</sup> hematologic malignancies,<sup>85</sup> organ transplant recipients, and congenital immunodeficiencies.<sup>86,87</sup> Mucocutaneous HSV infections in the immunocompromised host may be associated with prolonged local symptoms, systemic complaints, and a prolonged viral shedding beyond 30 days. Atypical infections may present with the following features:

- **Hyperkeratotic, verrucous (wart) lesions<sup>82,84</sup>:** In patients with advanced HIV infection, HSV may present as verrucous or warty lesions. Sometimes, the genital lesions of HSV acquire a large size, become papillomatous with a verrucous surface and may closely mimic condyloma acuminata or verrucous carcinoma. The histopathology, however, is characteristic and shows acantholytic and giant cells.
- **Vegetating plaques<sup>86</sup>:** Expanding, confluent, vegetating plaques with ulceration and a yellow exudate have been reported due to HSV genital infection.
- **Chronic, persistent ulceration:** Extremely painful, persistent, large, necrotizing ulcerated areas involving the whole perineum in females or the prepuce, glans, shaft of the penis, and pubic region in male.
- **Generalized papular eruptions:** Generalized exanthematous eruption can occur rarely as a result of dissemination in an immunocompromised host. This should be considered a medical emergency.

## Complications of Genital Herpes

Complications of genital herpes are nearly always associated with primary disease and are usually more severe in women than in men. Psychological, central nervous system (CNS) complications and secondary microbial infections are the commonest (Table 28.6).

### ASEPTIC MENINGITIS

HSV has been isolated from CSF of 0.5–3% of patients presenting with aseptic meningitis. HSV-2 is more commonly isolated than HSV-1.<sup>88</sup>

Genital lesions are present in only about one-third of the patients with HSV-2 meningitis. HSV can also be isolated from CSF of otherwise normal individuals. About 36% of women and 13% of men with primary HSV-2 genital infection develop this complication.<sup>67</sup> Genital lesions precede meningitis by about 1 week (range 3–12 days).<sup>89</sup> The symptoms of aseptic meningitis

include headache, rigid neck, vomiting, photophobia, malaise, and fever. The symptoms usually peak within 2–4 days and then gradually subside over 2–3 days. The CSF demonstrates a lymphocytic pleocytosis ranging from 5 to more than 1000/mm<sup>3</sup> (median 300–400/mm<sup>3</sup>) with a raised glucose (more than 50% of the blood glucose). HSV-2 meningitis resolves fully in the majority of individuals without any neurological damage.<sup>67</sup> Patients may occasionally present with aseptic meningitis as the sole presenting sign of new HSV-2 acquisition; in these cases, detecting the virus in the CSF and the lack of serum antibodies to the autologous virus type is diagnostic.

In primary genital herpes associated meningitis, transient neurological complications, such as urinary retention, dysesthesia, paraesthesias, neuralgias, motor weakness, paraparesis, concentration difficulties, periodic headache, and impaired hearing have been reported.<sup>89</sup> About 20–30% patients may have recurrent meningitis (benign recurrent lymphocytic meningitis or Mollaret meningitis).<sup>89</sup> There are no controlled trials for the use of intravenous (IV) acyclovir in the treatment of established HSV meningitis; however, it is recommended that symptomatic hospitalized patients be treated with IV Acyclovir 5 mg/kg 8 hourly and switched to oral antivirals preferably valacyclovir once symptoms have resolved.

### RADICULOMYELOPATHY

This is characterized by symptoms of sensory and autonomic nervous system dysfunction; numbness, paresthesia, neuralgic pain of the buttock, perineum or lower limbs, urinary retention, constipation and/or impotence. Clinical signs include sacral anesthesia, hyperesthesia, reduced perineal, and bulbocavernous reflexes, reduced rectal sphincter tone and bladder distension. Pleocytosis, elevated protein, and lower glucose may occur in the CSF.<sup>88</sup> Symptoms gradually resolve over days to weeks. Sometimes, residual urinary dysfunction, hyperesthesia of the lower extremities and weakness may persist for months.<sup>88</sup> The condition is particularly common in homosexuals with HSV proctitis.<sup>90</sup> Heterosexual women with primary genital herpes are the next most common subgroup prone to this complication.<sup>66</sup> Urinary retention in herpes genitalis predominantly occurs in females about 4 days after the appearance of lesions<sup>88</sup> and recovers in 3 days to 3 weeks. It is not clear whether demyelination is due directly to viral inflammation or indirectly to post-infectious inflammation. In reactivation disease, neuralgic pain and/or dysesthesia can occur in the form of prodromal symptoms at the site of the oncoming lesions or sometimes at a distal site within the distribution of the same ganglion. In abortive episodes, patients may experience only prodromes with no subsequent lesions. Rarely, the typical episodic prodromal pain of recurrent HSV infection acquires a chronic persistent course resembling post-herpetic neuralgia of herpes zoster, which may be associated with neurological deficit.<sup>88</sup>

### HSV ENCEPHALITIS

HSV infection is the most common cause of the sporadic fatal encephalitis.<sup>91</sup> The manifestations depend on the areas of the brain

**Table 28.6:** Major Sequelae of Genital Herpes

- |       |  |
|-------|--|
| (i)   | Psychological morbidity associated with recurrences                                  |
| (ii)  | Psychological morbidity related to fear of transmission to partner or fetus/newborn  |
| (iii) | Systemic complications such as aseptic meningitis or urinary retention               |
| (iv)  | Disseminated infection, mainly in immunocompromised host or in pregnancy (very rare) |
| (v)   | Transmission to the newborn (potentially fatal, fortunately rare)                    |
| (vi)  | Increased risk of acquiring/transmitting HIV infections                              |

affected. The clinical features include fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurological findings. The mortality among untreated patients is up to 76% and only 2.5% of those who survive regain normal neurologic function.<sup>91</sup> A number of genetic predispositions to the development of HSV encephalitis have been described.

### DISSEMINATED INFECTION

This is seen in immunocompromised hosts such as post-organ transplantation, malignancy, malnutrition, alcoholism, pregnancy, or in the neonate. It is also seen in patients with cutaneous disorders such as burns or eczema. The most important factor in dissemination seems to be cell-mediated immune deficiency. The dissemination could be mucocutaneous, visceral or both. Sometimes, dissemination occurs in immunocompromised patients (e.g., AIDS) with acyclovir-resistant HSV infection. These patients respond to foscarnet therapy.<sup>92</sup> The incidence of systemic dissemination in autopsy studies has been found to be up to 6%. The esophagus is the most common organ involved, and patients present with odynophagia, dysphagia, retrosternal pain, weight loss, and fever. Other presentations of systemic involvement include monoarticular arthritis, hepatitis, thrombocytopenia, and myoglobinuria.

### EXTRAGENITAL LESIONS

Extragenital lesions are located mainly on the buttocks, groin or thigh. Rarely, fingertips or eyes can be involved. Majority of the extragenital lesions develop by autoinoculation of virus or by viral reactivation in another part of the affected dermatome. Extragenital lesions are principally thought to be due to autoinoculation into distant sites and not due to viremic spread.

### PELVIC INFLAMMATORY DISEASE (PID)

PID can occur due to both HSV-1 and HSV-2 as a result of local spread. It should be considered in a patient with primary genital herpes presenting with lower abdominal pain and adnexal uterine tenderness. Other causes should always be considered and excluded.

### SECONDARY MICROBIAL INFECTION

Bacterial superinfection is uncommon in immunocompetent patients. In contrast, vaginal fungal infection is frequently seen during the course of primary genital herpes, particularly in the 2nd week and characterized by a change in the vaginal discharge and re-emergence of vulval itching and irritation.

## Genital Herpes and HIV

Genital herpes is the most common STD in HIV seropositive individuals. Seventy percent of the HIV-positives in the developed world and 95% in the developing world have HSV-2 antibodies.<sup>93,94</sup> The frequency of HIV seropositivity in genital herpes patients has varied from 0.5% (1995) to 20% (1999)

in various parts of India.<sup>28–30</sup> In HIV-positive heterosexuals in south London, UK 43% of women and 38% of men had genital ulcers caused by HSV.<sup>95</sup> The seroprevalence of HSV-2 in USA has been 81% in HIV-positive homosexual and bisexual men.<sup>93</sup> The HIV and HSV co-infection in Haitian women is 88% and in CSWs from Zaire is 95%. In male factory workers in Zimbabwe, HSV-2 seroprevalence was 35.7% among HIV-negative subjects but 82.7% among HIV-positive subjects.<sup>96</sup> Recent studies have shown that HSV-2 infection increases the risk of HIV acquisition among women (threefold), heterosexual men (two-fold) and homosexual men (1.7-fold).<sup>97</sup>

### GENITAL HERPES FACILITATES HIV TRANSMISSION

The topic of interaction between various STIs and HIV is discussed elsewhere (see Chapter 84, “Sexually Transmitted Infections in HIV-Infected Patients”). In brief, epidemiological and biological evidence suggests enhanced HIV transmission in presence of genital ulcers due to genital herpes and other STIs. Genital ulcers may facilitate HIV transmission through the reduced epithelial barrier and infiltration of CD4+ lymphocytes in herpetic lesions that are possible targets for HIV attachment and entry.<sup>98</sup> HIV-1 virions can consistently be detected in genital ulcers caused by HSV-2, which suggests that genital herpes infection is likely to increase the efficiency of sexual transmission of HIV-1.<sup>99</sup> It is possible that the antigenic stimulation of mucosal sites by reactivation of HSV can increase HIV-1 replication on mucosal surfaces. HSV also accelerates the progression of HIV disease. Acute episodes of HSV infection can stimulate HIV replication with increased HIV viral RNA levels detectable in the plasma in individuals not on HAART.<sup>100,101</sup>

### HSV SUPPRESSION TO LIMIT HIV PROGRESSION

Suppressive antiviral therapy in HIV-infected people with detectable viral loads has been shown to decrease the levels of HIV viremia between  $\frac{1}{4}$  and  $\frac{1}{2}$  log.<sup>102</sup> Such a strategy will impact on the progression of HIV and potentially delay the need for antiretroviral treatment. A large RCT in early HIV (those individuals not on HAART and with CD4 counts above 250) has shown that standard doses of suppressive antiviral therapy (acyclovir 400 mg bd) will sustain CD4 counts above accepted treatment levels and this effect reduced the need for HAART at 2 years by 16% in the treatment group.<sup>103</sup>

### Clinical Manifestations

The severity of HSV infection increases in presence of immunosuppression. Necrotic ulceration may appear at unusual sites and more extensive and chronic lesions may occur (Fig. 28.8). Dissemination, both mucocutaneous and systemic, are more common in HIV seropositive individuals with HSV-2 infection. Esophagitis, pneumonitis, and hepatitis can occur. Vegetating (Fig. 28.9), verrucous or disseminated maculopapular eruptions can occur (*vide supra*).

**Fig. 28.9:** Vegetating long standing lesions of genital herpes in HIV seropositive patient. *Courtesy: DG Saple, Mumbai, India.*

## HSV Shedding in HIV Infection

Asymptomatic HSV shedding (or more appropriately, microrecurrences) occurs four times more commonly in HIV seropositive than in HIV seronegative women.<sup>104</sup> Asymptomatic perianal HSV shedding is also more commonly seen in HIV seropositive individuals.<sup>105</sup> An inverse correlation exists between the CD4 count and the rate of genital HSV-2 shedding and a direct correlation between plasma HIV RNA and shedding. Sub-clinical HSV shedding is almost certainly associated with cutaneous or mucosal ulceration, however, it may be clinically inapparent.<sup>106,107</sup>

## Laboratory Diagnosis of Genital HSV Infections

Despite the frequent occurrence of atypical disease genital herpes is often diagnosed on clinical grounds alone—most guidelines advise that where possible laboratory confirmation of the diagnosis should be attempted. This may also be necessary in a patient with predominantly asymptomatic disease.<sup>108</sup> The majority of patients with genital herpes may present with atypical lesions that are easily confused with other genital dermatoses. This is particularly the case in those with HIV infection. The success of laboratory diagnostic methods (Table 28.7) is dependent on a number of factors. Viral titers (higher in primary episodes, in the immunocompromised, and in early lesions), sampling technique, the use of appropriate specimens, transport, and the methodology selected.<sup>61</sup>

## COLLECTION OF SPECIMENS

HSV can be isolated from mucocutaneous genital lesions.

The sensitivity of culture greatly varies according to lesions chosen for specimen collection (Table 28.8).<sup>109</sup> For specimen collection, a large vesicle should be chosen and the fluid gathered onto a cotton-tipped swab, or a tuberculin syringe can be used

**Table 28.7:** Laboratory/Serological Techniques in the Diagnosis of Genital Herpes Infection

### 1. Laboratory techniques:

- (a) Viral culture
  - Isolation of the virus in cell culture
  - Allows for testing for antiviral susceptibility
  - Modified culture techniques
- (b) HSV direct detection tests
  - Cytology
  - Electron microscopy
  - HSV antigen detection
  - HSV *in situ* hybridization
  - HSV PCR

### 2. Serological techniques

- (a) Functional antibody assay
  - Neutralizing antibody assay
  - Complement fixation
- (b) Solid phase binding assays
  - Reverse passive hemagglutination
  - Indirect fluorescence antibody assay
  - Enzyme immunoassay
  - Antibody typing by IFA or EIA
- (c) Type-specific immunoassay
  - Protein-specific immunoassays
  - Western blot (immunoblot)

to aspirate the fluid.<sup>109</sup> If a large vesicle is not present, then the exudate of a small vesicle or open lesion is collected by vigorously rubbing with a cotton-tipped swab on a wire shaft. To collect cervical specimens, the swab should be taken from ectocervix and the entry of the endocervical canal, as HSV involves squamous rather than columnar epithelial cells. The specimen should be placed immediately into vials containing 1 ml of viral transport medium and should be kept at 4°C until cultured. Freezing of specimens is associated with a loss of culture isolation but is preferred to keeping samples for extended periods at 4°C and is advised if delays beyond 48 hours are anticipated.

## CULTURE

Isolation of HSV in cell culture was tillied; recently regarded as the “gold standard” for the diagnosis of acute HSV infections. Commonly used human diploid fibroblast lines such as MRC-5 are well-characterized for HSV growth and take 12–18 hours for HSV replication. Cytopathic effect (CPE) appears in 2–3 days after inoculation. Other viruses may exhibit a CPE similar to HSV. Thus isolates require confirmation.

The confirmatory tests are based on various methods like neutralization with type-specific antisera, immunological assays, such as immunofluorescence, and nucleic acid hybridization. HSV-1 and HSV-2 can be differentiated by using monoclonal antibodies directed to type-specific antigens in enzyme immunoassay (EIA) or fluorescence immunoassay. Advantages include high specificity and testing for antiviral susceptibility. However levels of viral shedding (e.g., in first vs. recurrent episodes and in early vs. late presentations) can significantly influence sensitivity. Delayed

**Table 28.8:** Sensitivity of Culture in Specimens Collected from Lesions at Different Stages

Nature of lesion	Sensitivity
Fresh vesicle (primary)	>90%
Pustular lesion (primary)	70–80%
Ulcerative lesion (primary)	70–80%
Recurrent infection	50%
Crusted lesion	25%

sample processing and lack of refrigeration after sample collection can decrease diagnostic yield.<sup>110,111</sup>

### HSV DIRECT DETECTION TESTS

Though cell culture techniques are highly sensitive, they may take many days for growth and confirmation of HSV. Negative results can take beyond a week. In many clinical situations a rapid diagnosis can be extremely helpful. Cytology, electron microscopy, and HSV antigen/DNA detection technique can be used for rapid HSV detection.

#### Cytology

It is 30–80% sensitive and is not routinely recommended for diagnosis (discussed earlier).

#### Electron Microscopy

It can be used for visualization of negatively stained HSV virions from vesicle fluid. The drawback of EM is, however, that it requires expensive equipment and trained personnel to perform the technique. Sensitivity is low and differentiation from other herpes virions is not possible.

### HSV Antigen Detection

- **Immunofluorescence:** Detection of HSV antigen can be done by binding of antibodies conjugated with fluorescent dyes (direct fluorescent antibody or DFA test). The sensitivity of DFA test for the detection of HSV in genital specimens varies between 70% and 90% of culture-positive specimens.<sup>109</sup> The technique requires a fluorescent microscope.
- **Immunoperoxidase (IP) tests:** Here, anti-HSV antibodies are conjugated with enzyme peroxidase and treated with the diaminobenzidine, which reacts with peroxidase enzyme to form a reddish brown complex in the sample where the antibody is bound to the viral antigen.
- **Enzyme immunoassay (EIA):** Two types of microtiter plate ELISA procedures for the direct detection of HSV antigens are available. (i) Antigen capturing: HSV antigen in clinical specimens is captured by polyclonal anti-HSV antibodies immobilized in microtiter plate walls. The im-

mobilized antigen is then treated with a biotin-labeled mouse monoclonal antibody. After adding streptavidin horseradish peroxidase conjugate and chromogenic substrate, a colored reaction product is obtained. (ii) Antigen–antibody amplification: Specimens are added to wells coated with mouse monoclonal antibody and an alkaline phosphatase conjugate. HSV antigen present in the specimens will react with the antibody and become immobilized. The bound enzyme is then treated with a substrate giving a colorless product, which is then treated with an amplifier. This produces a colored reaction product. The sensitivity of ELISA is 70–95% and specificity is 94–100% for symptomatic patients and offers a rapid diagnostic tool in settings with limited laboratory facilities.

- **Rapid assay:** HSV antigen is extracted from the clinical specimen with a buffered solution. The extract is added to a test device and any antigen present is immobilized on a membrane. When treated with peroxidase-labeled anti-HSV monoclonal antibody with a substrate, a colored spot is obtained on the membrane. Inability to type HSV is a severe limitation of ELISA.

### HSV-DNA Detection (DNA Hybridization)

The sensitivity of this test is equal to that of HSV antigen detection tests in symptomatic HSV infection but not in asymptomatic HSV infections. The detection of HSV by DNA hybridization is done using radiolabeled or biotin-labeled probes.

### HSV-PCR

HSV DNA detection by real-time PCR increases HSV detection rates in mucocutaneous swabs by 11–71% compared with virus culture and is recommended as the preferred diagnostic method.<sup>112–114</sup> Real-time PCR can tolerate less stringent conditions for sample storage and transport than virus culture, and allows the rapid detection and typing of HSV with a lower risk of contamination than traditional PCR assays. Compared to culture PCR is better for early and late presentations as well as those with initial or recurrent disease. A particular benefit is that a negative result is available within a few hours if required.

### Serological Testing

Serological testing is not routinely recommended in asymptomatic patients but is indicated in the following groups<sup>115–121</sup>:

- History of recurrent or atypical genital disease when direct virus detection methods have been negative. HSV-2 antibodies are supportive of a diagnosis of genital herpes; HSV-1 antibodies do not differentiate between genital and oropharyngeal infection.
- First-episode genital herpes, where differentiating between primary and established infection guides counseling and management. At the onset of symptoms, the absence of HSV

IgG against the virus type detected in the genital lesion is consistent with a primary infection.<sup>115</sup> Seroconversion should be demonstrated at follow-up.

- Sexual partners of patients with genital herpes, where concerns are raised about transmission. Serodiscordant couples can be counseled about strategies to reduce the risk of onward transmission.
- Testing of asymptomatic pregnant women is not routinely recommended, but is indicated when there is a history of genital herpes in the partner.<sup>122–124</sup> HSV-1 and/or HSV-2 seronegative women should be counseled about abstinence or at least avoiding unprotected sex in the last trimester to avoid acquisition of either virus type during pregnancy.

Limited data suggest an increased risk of perinatal HIV transmission among HSV-2 seropositive HIV-infected women.<sup>125,126</sup> As evidence is not consistent, testing of HIV-positive pregnant women is not routinely recommended.<sup>127</sup>

HSV serological assays should be used that detect antibodies against the antigenically unique glycoproteins gG1 and gG2.<sup>128,129</sup> Non-type-specific HSV antibody assays are of no value in the management of genital herpes. The main utility of these commercially developed serological methods is the identification of undiagnosed HSV-2 infection.

Western blot (WB) is the diagnostic gold-standard. It is >97% sensitive and >98% specific, but is labor-intensive and not commercially available.<sup>130,131</sup>

Several commercial (e.g., Focus HerpeSelect ELISA and Immunoblot; Kalon HSV-2 assay) and in-house assays are available, with reported sensitivities >95% and generally high specificities. False negative results are more likely to occur in early infection and can be resolved by repeat testing. False positive results have been observed in populations with low prevalence and in some African cohorts.<sup>132</sup> Rapid point of care tests are available (e.g., Biokit HSV-2 assay, previously POCKIT™ HSV-2, with sensitivity and specificity >92%) and new assays are being developed.<sup>133</sup>

HSV seroprevalence rates, presence of risk factors for genital herpes, and clinical history influence the positive predictive value (PPV) of HSV type-specific serology and should guide testing and result interpretation. Type-specific HSV IgG becomes detectable 2 weeks to 3 months after the onset of symptoms and is commonly negative in early presentations.<sup>126</sup> Where clinically indicated, follow-up samples should be taken to demonstrate seroconversion. Paired serology combined with virus isolation can be used for disease classification (Table 28.4). HSV IgM testing substantially increases the ability to detect early infection in patients who lack detectable IgG,<sup>134</sup> however has limited availability in routine diagnostic settings. In addition, IgM testing can also be positive during reactivation of disease and negative during primary disease, and is not viral-type specific. Because of these limitations, the test cannot be recommended in routine clinical practice.

## Treatment

### DRUGS

#### Acyclovir

Acyclovir is a white crystalline powder soluble in water.<sup>135</sup> It is highly active against HSV-1, slightly less active against HSV-2 and approximately eightfold less active against the varicella zoster virus. It is also active against Epstein–Barr virus and human herpes virus-6, but not against cytomegalovirus. The antiviral activity of acyclovir is due to intracellular conversion of acyclovir, by viral thymidine kinase, to the monophosphate with subsequent conversion by cellular enzymes to the diphosphate and the active triphosphate. This active form inhibits viral DNA synthesis and replication by inhibiting the herpes virus DNA polymerase enzyme as well as by being incorporated into the viral DNA. The whole process is highly selective for infected cells. Acyclovir has no activity against latent virus, but it inhibits latent HSV at an early stage of reactivation.

#### Adverse Effects

The most frequent adverse effects of acyclovir reported during clinical trials were nausea, vomiting, and headache. Serious adverse drug reactions and cumulative toxicity are rare although renal crystallization and neutropenia have been reported.

#### Resistance<sup>136</sup>

HSV develops resistance to acyclovir *in vitro* and *in vivo* by selection of mutants deficient in thymidine kinase. Other mechanisms of acyclovir resistance include altered substrate specificity of thymidine kinase and reduced sensitivity of viral DNA polymerase. Although, there have been many reports of treatment failure, resistance has never been a major problem in genital herpes. This can be explained on the basis of low incidence of resistant mutants *in vivo* and because viruses deficient in thymidine kinase generally appear to be of diminished virulence with reduced infectivity and latency. Resistant viruses are most troublesome in immunocompromised patients. HSV resistant to acyclovir because of absence of thymidine kinase may be cross-resistant to other antivirals phosphorylated by this enzyme, such as brivudine, idoxuridine, and ganciclovir. Viruses resistant due to altered substrate specificity of thymidine kinase may also be resistant to brivudine.

#### Pharmacokinetics

Acyclovir can be administered in oral, intravenous or topical formulations.<sup>137</sup> The bioavailability after oral administration is only 15–30% and a 200 mg oral dose results in a peak plasma concentration of 0.4–0.8 mg/mL approximately 1.5 hour after administration. The plasma half-life is 2.1–3.5 hours in patients with normal renal function. It is eliminated largely unmetabolized by the renal route. In patients with compromised renal function, the dosage should be reduced. With 5% acyclovir ointment in

polyethylene glycol base, application results in detectable drug concentrations in the lesion.

### Acyclovir in Pregnancy

Acyclovir is not teratogenic in the mouse or rabbit.<sup>138,139</sup> In non-standard tests in which the drug was given in rats for only 1 day during the period of major organogenesis, fetal abnormalities, such as head and tail abnormalities, were observed, and was associated with toxicity to the maternal rat.<sup>140</sup> The clinical relevance of these experiments is unknown. The acyclovir in pregnancy register has now been closed but in its final report data on 1129 pregnancies is reported. This shows the incidence of congenital anomalies and fetal loss did not appear to be higher than the general population.<sup>138</sup> Transient neutropenia in some neonates of questionable significance has been reported in a third trimester treatment study.<sup>141</sup> Acyclovir is excreted in breast milk following oral administration. Although most formularies advise caution to be exercised when prescribing to breastfeeding mothers it is generally considered a safe drug.<sup>135</sup>

### Famciclovir/Penciclovir

Like acyclovir, penciclovir is an acyclic guanosine analog and inhibits HSV DNA synthesis by short-chain termination. Penciclovir is poorly absorbed orally, but is active intravenously. Its diacetate ester, famciclovir, developed for oral use, is converted, after absorption, in the intestinal wall and liver, to the active compound, penciclovir. Penciclovir is eliminated unchanged by the liver. The plasma half-life for penciclovir is identical to that of acyclovir (2.5 hour). The initial phosphorylation to penciclovir monophosphate is carried out by HSV-induced thymidine kinase (like acyclovir). Phosphorylation to di- or tri-phosphate forms is carried out by cellular kinases. Penciclovir triphosphate has antiviral activities against HSV-1, HSV-2, VZV, EBV, and hepatitis B virus. It inhibits viral DNA polymerase. There are some quantitative differences in the mechanisms of action between penciclovir and acyclovir. Compared with acyclovir, penciclovir is preferentially taken up and phosphorylated by HSV and VZV infected cells. Penciclovir triphosphate has a very prolonged intracellular half-life in infected cells (7–20 hours vs. 0.7–1 hour for acyclovir triphosphate). However, more penciclovir triphosphate is required for inhibition of HSV DNA polymerase compared with acyclovir triphosphate.<sup>142</sup> Studies in mice have shown that famciclovir (which is converted into penciclovir after absorption) has different effects on the course of the disease when compared with acyclovir and valacyclovir. In mice with experimentally produced first episode of genital herpes, immediately after stopping valacyclovir, the disease recurred, while famciclovir resulted in a prolonged suppression with no recurrences.<sup>143</sup> However, these effects have not been confirmed in humans.<sup>144</sup> and a single study in first episodes of herpes comparing high-dose famciclovir to standard therapy with other antivirals showed no impact on the natural history of the disease. The majority of acyclovir-resistant HSV clinical isolates will also

be resistant to penciclovir.<sup>105</sup> Randomized placebo controlled trials of famciclovir in the treatment of active recurrent genital herpes have demonstrated that 125, 250 or 500 mg twice daily doses of famciclovir reduce the duration of viral shedding, time required for appearance of crusting, time required for complete healing and duration of symptoms.<sup>105</sup> In a randomized controlled trial, oral famciclovir in dosages of 125 or 250 mg, three times daily, or 250 mg twice daily given for 52 weeks was found safe, effective and well-tolerated.<sup>145</sup> Oral famciclovir has also been used successfully for suppression of recurrences in genital herpes with frequent episodes.<sup>142</sup>

### Adverse Effects

Famciclovir is a well-tolerated drug and serious side effects are uncommon. Prolonged, high-dose administration of famciclovir to rats was associated with an increased incidence of mammary adenocarcinomas in female rats. The clinical significance of this is unknown. Testicular toxicity was observed in rats, mice, and dogs following repeated administration of famciclovir or penciclovir. These effects were only noted at doses higher than those used in human studies and long-term studies in healthy males have shown no impact on sperm function. There is limited data of its use in pregnancy.

### Valacyclovir

Valacyclovir, a prodrug of acyclovir (L-valyl ester of acyclovir), was developed mainly to improve its bioavailability. Oral valacyclovir is rapidly absorbed and almost completely converted to acyclovir in the intestine and liver. Oral valacyclovir results in a 3–5-fold greater bioavailability (15–30% for acyclovir vs. 54% for valacyclovir<sup>146</sup>). The pharmacokinetics and toxicity of valacyclovir are comparable to that of acyclovir. Thrombotic microangiopathy has been observed in about 3% of immunocompromised patients receiving 8 g/day of valacyclovir for prevention of CMV disease. This, however, has not been observed for lower doses used for varicella or HSV infection.<sup>147</sup> Two placebo-controlled comparative trials of acyclovir and valacyclovir have shown no difference in efficacy of both the drugs in recurrent genital herpes. The dosages of valacyclovir used in these studies were 1000 and 500 mg twice daily and 200 mg of acyclovir five times a day with no difference in the outcome. The only advantage found with valacyclovir was its convenient bid dosing.<sup>148,149</sup> Valacyclovir (500 mg once daily) has also been shown to suppress recurrent genital herpes. Valacyclovir has been used to suppress patients with, severe (>10 episodes a year), moderate and mild disease as well as those with only serologically apparent disease—all these trials again confirm efficacy.<sup>150–152</sup>

### Ganciclovir

It is a nucleoside analog that is similar in structure to acyclovir. However, it is more active against CMV. It has good activity against HSV-1, HSV-2, VZV, and EBV and is also active

against HHV-6 and HBV. The drug is discussed elsewhere (See Chapter 33, “Human Cytomegalovirus Infection”).

### Idoxuridine

It is a nucleoside analog, active against HSV-1, HSV-2, VZV, and poxviruses.<sup>101</sup> It is converted into idoxuridine triphosphate, which inhibits viral DNA polymerases and also acts as a chain terminator. It is available as 1% ophthalmic solution in distilled water and as a 0.5% ophthalmic ointment in a petrolatum base. It is approved for treatment of HSV keratitis. Idoxuridine in DMSO has been reported to have beneficial effects on mucocutaneous HSV infections.<sup>153</sup> Systemic use has been abandoned because of toxicities.

### Trifluridine

It is a pyrimidine nucleoside analog with activity against HSV-1, HSV-2, CMV, and vaccinia.<sup>154</sup> Topical trifluridine, either alone or in combination with interferon, has been reported to be beneficial in the treatment of acyclovir-resistant mucocutaneous HSV infections in patients with AIDS.

### Cidofovir

This is an acyclic nucleoside phosphonate, which unlike acyclovir, is phosphorylated only by cellular enzymes.<sup>155</sup> Hence, it is active against HSV with deficient or altered thymidine kinase enzyme. Topical and i.v. cidofovir have been successfully used for the treatment of acyclovir-resistant HSV lesions in AIDS or marrow transplantation patients.<sup>156</sup> A double blind placebo controlled trial of topical 0.3% or 1% cidofovir gel in 30 patients with AIDS who did not respond to acyclovir therapy showed that lesions healed by at least 50% in 50% of patients who received cidofovir.<sup>157</sup> As the i.v. administration of cidofovir is associated with systemic side effects, in particular renal toxicity, topical therapy is preferred.

### Foscarnet

It is a phosphonate viral DNA polymerase inhibitor. Intravenous administration is associated with systemic toxicity. Foscarnet has been the preferred agent for patients with acyclovir-resistant HSV infection. In one study of 26 patients with acyclovir-resistant HSV infection the lesions healed in 81% of the patients with foscarnet.<sup>158</sup> The most common toxicities are renal insufficiency and metabolic disturbances (mainly hypophosphatemia). HSV resistance to foscarnet can occur after prolonged use.<sup>159</sup> In such a situation, the addition of acyclovir to the treatment regimen may be beneficial.<sup>155</sup>

### Other Drugs

**n-Docosanol:** This is also known as behenyl alcohol. It is produced by high pressure, catalytic hydrogenization of a mixture of fatty acids derived from extracts of various plant sources. 10% cream of n-Docosanol has been found to be effective in recurrent HSV infection in experimental models.

**Imiquimod and resiquimod:** Case reports of these agents suggest some limited value in managing HSV infection. Such effects have not been clearly demonstrated in well-controlled studies.

**Isoprinosine:** This agent was widely promoted as improving the hosts own immune control of HSV. A head-to-head study compared Isoprinosine to Acyclovir and placebo and found that over a 6 month period the studied dose (Isoprinosine 500 mg twice daily) had no therapeutic value.<sup>160</sup>

**Helicase primase inhibitors:** A number of orally available agents have been identified that interfere with the activity of the helicase primase complex at key stages of DNA replication.<sup>161</sup> Development to date has demonstrated that these agents in the laboratory can be extremely powerful inhibitors of HSV replication. However, work to date has not yielded clinically useful compounds. Phase two studies are currently underway with newer agents in this family of drugs.

## CLINICAL MANAGEMENT

### Management of First Episode

Patients presenting early in the disease (within 5 days of the start of the episode or while new lesions are still forming), patients who have systemic symptoms, complications or are immunocompromised should be given oral antivirals (Table 28.9).<sup>162,163</sup> Acyclovir, valacyclovir, and famciclovir reduce the severity, viral shedding, itching, average healing time and frequency of new lesion formation during the acute episode.<sup>164</sup> Antiviral therapy, however, does not alter the long-term natural history of the disease. The duration of treatment varies in different recommended treatment guidelines (Table 28.9) with a range of 5–10 days, however there are no comparative studies available. Since acquisition episodes can occasionally be prolonged it would be advisable to continue therapy while new lesions are forming or the patient remains systemically unwell. Intravenous acyclovir should be considered when the patient is unable to swallow, when oral administration may not guarantee absorption (e.g., vomiting) and if severe complications such as neurological disease or dissemination is occurring when guaranteed delivery of the agent is essential and levels that are higher than may be achieved orally are required.<sup>162</sup> Symptomatic/supportive treatment in the form of bathing in salt water (e.g., half a cup of ordinary household salt in the bath) will help relieve the pain. Topical anesthetic jelly can be used; however, there is a theoretical risk of sensitization although this is unlikely over the short duration for which it is recommended. Analgesics should also be offered. During an acquisition episode the patient will be developing a full immune response but does remain vulnerable to further inoculation of the virus at distant sites. Advice on washing hands carefully after treating lesions and the use of a separate towel for the genital area is often given.

### Management of Recurrent Genital Herpes

Recurrences of genital herpes generally cause minor symptoms, which are self limiting. For most patients, supportive therapy in

**Table 28.9:** Guidelines for Management of Genital Herpes

<b>(a) First episode</b>	
(i) CDC guidelines 2010	<ul style="list-style-type: none"> <li>Acyclovir 400 mg orally, three times a day for 7–10 days, or</li> <li>Acyclovir 200 mg orally, five times a day for 7–10 days, or</li> <li>Famciclovir 250 mg orally, three times a day for 7–10 days, or</li> <li>Valacyclovir 1 g orally, two times a day for 7–10 days</li> </ul>

<b>(b) Suppressive therapy for recurrent genital herpes (for recurrence rate &gt; 6 per year, the effect of therapy should be assessed after completion of 1 year)</b>	
(i) CDC guidelines 2010	<ul style="list-style-type: none"> <li>Acyclovir 400 mg orally, two times a day, or</li> <li>Famciclovir 250 mg orally, two times a day, or</li> <li>Valacyclovir 500 mg orally, once a day, or</li> <li>Valacyclovir 1.0 g orally, once a day</li> </ul>
(ii) UK National guidelines 2007	<ul style="list-style-type: none"> <li>Acyclovir 200 mg orally, four times a day, or</li> <li>Acyclovir 400 mg orally, two times a day, or</li> <li>Famciclovir 250 mg orally, two times a day, or</li> <li>Valacyclovir 500 mg orally, once a day</li> </ul>

(iii) IUSTI/WHO European guidelines 2010

- Acyclovir 200 mg orally, four times a day, or
- Acyclovir 400 mg orally, two times a day, or
- Valacyclovir 500 mg orally, once a day (for <10 recurrences/year)
- Valacyclovir 250 mg orally two times a day or 1.0 g orally once a day (for >10 recurrences/year)

(iv) Australian guidelines (AHMF) 2007

- Acyclovir 200 mg orally, 2–3 times a day (considered in pregnancy), or
- Acyclovir 400 mg orally, two times a day, or
- Famciclovir 250 mg orally, two times a day, or
- Valacyclovir 250 mg orally two times a day or 500 mg orally once a day (for <10 recurrences/year), or
- Valacyclovir 1.0 g orally once a day (for >10 recurrences/year)

**(c) Genital herpes in HIV infected individuals (and other immunocompromised states)**

(i) CDC guidelines 2010

For episodic therapy:

- Acyclovir 400 mg orally, three times a day for 5–10 days, or
- Famciclovir 500 mg orally, two times a day for 5–10 days, or
- Valacyclovir 1.0 g orally, two times a day for 5–10 days

For suppressive therapy

- Acyclovir 400–800 mg orally, 2–3 times a day, or
- Famciclovir 500 mg orally, two times a day, or
- Valacyclovir 500 mg orally, two times a day

(ii) UK National guidelines 2007

- Episodic and Suppressive regimes-same as CDC 2010,
- For resistant genital herpes-active lesions:
- Standard aciclovir therapy, if unresponsive,
- Acyclovir 800 mg five times a day, if still unresponsive,
- Topical trifluridine 8 hourly until complete healing (for accessible lesions), or
- IV foscarnet 50 mg/kg twice daily until complete healing (for inaccessible lesion)

(iii) IUSTI/WHO European guidelines 2010

Episodic therapy:

- Acyclovir 200–400 mg orally, five times a day, or
- Acyclovir 400–800 mg orally, three times a day, or
- Famciclovir 250–500 mg orally, three times a day, or
- Valacyclovir 500 mg–1.0 g orally, two times a day

Suppressive therapy:

- Acyclovir 400 mg orally, two times a day, or
- Valacyclovir 500 mg orally, two times a day, or
- Famciclovir 500 mg orally, two times a day

(iv) Australian guidelines (AHMF) 2007

Episodic:

- Valacyclovir 500 mg orally, two times a day for 5–10 days, or
- Famciclovir 500 mg orally, two times a day for 5–10 days

Suppressive:

- Valacyclovir 500 mg orally, two times a day, or
- Famciclovir 500 mg orally, two times a day

the form of simple analgesics, saline bathing and topical occlusion with petroleum jelly or a dry dressing is sufficient. Episodic antiviral therapy (oral acyclovir/valacyclovir/famciclovir) will reduce the duration and severity of the episode although in large studies the average reduction in duration is only by a median of 1–2 days and is only present when therapy is initiated early in the evolution of the recurrence.<sup>165–167</sup> Episodic therapy to be effective

must be initiated by patients at the first signs of a recurrence.<sup>167</sup> Although the newer antiviral agents (famciclovir and valacyclovir) have not been shown to be clinically superior to acyclovir in 5 days studies of episodic therapy,<sup>144,168</sup> a large body of work now shows that high-dose therapy with prodrugs over short durations, even down to 1–2 days is as effective as 5 days of therapy and significantly better than placebo in generating aborted lesions (lesions that do not progress beyond the prodromal to papular stages).<sup>168–173</sup> An impact on lesion abortion better than placebo has also been demonstrated with Acyclovir 800 mg tds when used for 2 days.<sup>174</sup> These studies all support the use of patient initiated, high dose, short episodes of therapy over the traditional longer 5 days courses.

**Suppressive therapy:** Daily antiviral therapy effectively suppresses recurrences. Prices for generic equivalents have in recent years fallen dramatically and most decisions around the initiation of therapy can now be based on clinical effectiveness and inconvenience for the patient. In assessing a patient for suppressive therapy it is important to assess not just the disease frequency (e.g., >6 recurrences/yr), the severity of each episode including the presence of disturbing prodromes, as well the greater effects that the disease has on the patient such as psychological and psychosexual impacts.<sup>163</sup> Suppressive regimens of antiviral medication decrease the frequency of genital herpes recurrences by up to 80% and 25–30% patients who receive suppressive therapy experience no further recurrences while on therapy.<sup>134</sup> One multi-centric 5-year trial of suppressive therapy with acyclovir in 1100 immunocompetent patients with >12 recurrences per year showed a reduction in the recurrence rate from 12.9 at baseline to 0.8 in year 5; 20% of the patients were recurrence free for all 5 years.<sup>137</sup> No significant adverse reactions were noted. Suppressive therapy has been shown in well-conducted studies to improve psychological well-being in patients with HSV. Suppressive therapy also decreases asymptomatic shedding by 85%<sup>175</sup> and has been shown to effectively prevent the sexual transmission of HSV to uninfected partners—the only large study that has looked at this in serodiscordant couples found that continuous suppressive valacyclovir in those with recurrent disease of less than 10 episodes/yr reduces transmission by approximately 50% in an 8 month follow-up period.<sup>120,176</sup>

**Convenience and cost.** Valacyclovir can be administered in once daily dosages,<sup>177,178</sup> and offers some advantage over acyclovir and famciclovir. Patients receiving suppressive therapy should be advised that antiviral therapy does not cure the underlying infection or completely halt asymptomatic viral shedding.<sup>179,180</sup>

**Safety.** Acyclovir has been used extensively for the last two decades for long-term suppression. A small cohort of patients has used it daily for over 10 years. While such long-term administration is not necessary in the majority of the patients, it is encouraging that the drug is well-tolerated.<sup>181,182</sup> Similarly experience with long-term use of both valacyclovir and famciclovir has also grown and both agents have good long-term safety records (more data is available for valacyclovir since this has been much more widely used). Decisions to discontinue suppressive

therapy once it has been initiated should be made jointly with the patient—most clinicians would not give suppressive therapy for a period of less than 6 months in the first instance although short duration therapy to cover a specific time period of concern for the patient is often valuable.

## Genital Herpes in HIV Infected Individuals (as well as Other Patients in Immunocompromised States)

Patients with HIV infection have more frequent and prolonged episodes with slower responses to acyclovir, even in the absence of overt acyclovir resistance. There is a substantial increase in the rate of subclinical shedding.<sup>104</sup> One double blind, placebo control trial of famciclovir in HIV-infected persons with genital HSV infection (dose 500 mg twice daily for 8 weeks) has shown significant reduction in symptoms associated with HSV infection and the symptomatic and asymptomatic shedding of HSV.<sup>183</sup> A study comparing suppressive therapy with acyclovir and valacyclovir revealed that both drugs are equally effective in suppressing the genital HSV in HIV-infected patients.<sup>184</sup> Studies do however show that twice daily therapy is superior in this group to once daily treatments.

The evidence base to make recommendations for therapy in this group is relatively limited and for many patients the general adage to double the dose of a drug and to give it for longer may not be necessary.<sup>185</sup>

The frequency of acyclovir resistance in HIV-infected patients appears low.<sup>157</sup> With the decline of HSV culture facilities, *in vitro* testing of HSV isolates for acyclovir susceptibility is extremely difficult to source. Genotypic assessment of HSV strains can yield some useful information about their susceptibility to different therapies but such determination is unreliable and presently only available in select research settings. HIV-positive patients with persistent HSV infection, unresponsive to high-dose acyclovir, should be tested for resistance.<sup>157,162</sup> Patients unresponsive to acyclovir therapy are often also resistant to valacyclovir and famciclovir—they can be treated with topical trifluridine 8 hourly or IV foscarnet 50 mg/kg twice daily until complete healing.<sup>127</sup> Every effort must be made to improve the patient's immune status to reduce the rate of recurrences needing multiple courses of acyclovir which could potentially result in development of ACV-resistant strains.

## HSV Latency and Antiviral Therapy

HSV latency is responsible for recurrences and persistent infection and is the main hurdle in the search for a true therapeutic “cure” for the disease.<sup>186</sup> Experimental studies in animals have shown that it is possible to limit the magnitude of latency (i.e., the number of latently infected neurons) by prompt administration of nucleoside analogs and helicase primase inhibitors to such an extent that subsequent recurrences may be less frequent. Human studies with high-dose therapies (intravenous acyclovir and prodrugs) have not been able to show such an effect; this

may be due to the late stages at which most patients present. A recent study of a vaginally administered antiviral (tenofovir)<sup>187</sup> showed that regular use in those at high risk of HSV diminished acquisitions by half.

### Effect of Antivirals on Asymptomatic Shedding

Controlled trials have shown a significant suppression of asymptomatic viral shedding with acyclovir suppressive therapy. One such trial showed that patients on suppressive therapy with acyclovir had asymptomatic shedding on 0.3% of days, in contrast, patients on placebo showed asymptomatic shedding on 6.9% of days when assessed by culture.<sup>180</sup> Similar trials with valacyclovir showed a decline in viral shedding from 15.3% of days in the placebo group to 0.7% of days in valacyclovir group.<sup>188</sup> Head-to-head studies between all antivirals have not been completed and where available the data often is from only one study. Current evidence indicates that suppressive antiviral therapy can reduce infectivity in most groups. Clinically, an impact on transmission has only been demonstrated with valacyclovir in the context of established serodiscordant heterosexual relationships outside of pregnancy.<sup>120</sup> However, many guidelines recommend the extension of this finding to many other groups.<sup>189</sup>

### Management of Genital Herpes in Pregnancy

Women with genital herpes infection in pregnancy are at risk of transmitting herpes to their baby at the time of delivery resulting in neonatal herpes infection. Over 95% of infected babies are born to women who are unaware that they have genital herpes. Neonatal herpes is a severe illness with a high mortality and morbidity even with prompt antiviral treatment.<sup>190,191</sup> According to IUSTI/WHO European guidelines 2010, following considerations should be taken into account for the management of pregnant women with first episode genital herpes.<sup>162</sup>

#### FIRST AND SECOND TRIMESTERS ACQUISITION

A significant risk of miscarriage is present. Management of the woman should be in line with her clinical condition and will often involve the use of either oral or intravenous acyclovir in standard doses. Providing that delivery does not ensue, the pregnancy should be managed expectantly and vaginal delivery anticipated. Daily suppressive acyclovir 400 mg tid from 36 weeks gestation may prevent HSV lesions at term and hence the need for delivery by Caesarean section.<sup>192–197</sup>

#### THIRD TRIMESTER ACQUISITION

Caesarean section should be considered for all women, particularly those developing symptoms within 6 weeks of delivery, as the risk of viral shedding in labor is very high. Daily suppressive aciclovir 400 mg tid from 36 weeks gestation may prevent HSV lesions

at term. If vaginal delivery is unavoidable, prolonged rupture of membranes and invasive procedures, including the use of scalp electrodes, should be avoided. Intrapartum IV acyclovir given to the mother and subsequently to the baby may be considered and the pediatrician should be informed.<sup>198</sup>

### MANAGEMENT OF PREGNANT WOMEN WITH RECURRENT GENITAL HERPES

Women with recurrent genital herpes should be informed that the risk of neonatal herpes is low. Symptomatic recurrences of genital herpes during the third trimester will be brief; vaginal delivery is appropriate if no lesions are present at delivery. For women with a history of recurrent genital herpes who would opt for a Caesarean section if they had HSV lesions at the onset of labor, daily suppressive acyclovir 400 mg tid from 36 weeks gestation may prevent HSV lesions at term and hence the need for delivery by Caesarean section.<sup>151,199</sup> If there are no genital lesions at delivery, there is no indication for a Caesarean section to prevent neonatal herpes. Sequential cultures or PCR during late gestation to predict viral shedding at term are not indicated.<sup>200</sup> The utility of taking cultures or PCR at delivery, in order to identify women who are asymptotically shedding HSV is unproven. Management of women with genital lesions at onset of labor Caesarean section may be considered for women with recurrent genital herpes lesions at the onset of labor but the risk of neonatal herpes following vaginal delivery is small and must be set against risks to the mother of Caesarean section. Evidence from the Netherlands shows that a conservative approach, allowing vaginal delivery in the presence of an anogenital lesion, has not been associated with a rise in numbers of neonatal HSV cases.<sup>201</sup> However, this approach can only be adopted if fully supported by obstetricians and neonatologists, and if consistent with local medico-legal advice. Clinical diagnosis of genital herpes at the time of labor correlates relatively poorly with HSV detection from genital sites by either culture or PCR and fails to identify women with asymptomatic HSV shedding.

### Management of Psychosocial Sequelae of HSV Infection

Many studies have suggested that there is a psychological morbidity associated with recurrent infection, which is not necessarily attributable to the physical restriction that frequently recurring infection may impose.<sup>202–205</sup> At the time of diagnosis, patients may experience anguish, helplessness, feelings of depression or rage (self-directed or focussed on the person who is suspected of transmitting the infection or on the diagnosing physician) and reduced self-esteem.<sup>206–209</sup> Patients with recurrent genital herpes may experience shame and guilt or withdraw from social interactions and intimate relationship because of concerns about undesirability, discovery, disapproval and rejection, leading to increasing isolation and withdrawal.<sup>210,211</sup> For most patients a diagnosis of genital herpes is often their first diagnosis of a chronic long-term condition and they will often consider it the worst

thing that has happened to them.<sup>212</sup> The physician should not be dismissive of the patient's disease and care should be taken to provide adequate, appropriate and timely support and counseling.

Counseling of patients should include a discussion on the following points:

- (a) Possible source(s) of infection
- (b) Natural history including risk of subclinical viral shedding
- (c) Future treatment options
- (d) Risk of transmission by sexual and other means
- (e) Risks of transmission to the fetus during pregnancy and the advisability of the obstetrician/midwife being informed
- (f) Sequelae of infected men infecting their uninfected partner during pregnancy

Antiviral suppression is an effective way to improve and manage psychosexual problems. There will be a small group of patients who will not adjust to their diagnosis, remain socially withdrawn and develop clinically significant depression or obsessive rumination concerning their disease. Timely referral for formal psychological support should be considered in these cases. It is widely advised that episodic therapy may aggravate psychosexual problems because of the need for patients to be constantly aware of the possible need to instigate therapy at the earliest sign of any symptoms.

## Vaccines

Many types of vaccines against HSV have been developed in an attempt to prevent acquisition or to modify the frequency and/

or severity of recurrences<sup>213,214</sup> (Table 28.10). Numerous forms of non-specific immune stimulation like BCG vaccine, levamisole, and vaccinia inoculation have been tried.<sup>8</sup> In animal studies, vaccine-induced immunity has failed to prevent viral replication in the genital tract and establishment of latent infection in sensory ganglia after experimental HSV challenge.<sup>215–217</sup> In spite of failure to provide sterilizing immunity and protect against infection, vaccines in experimental models do protect animals from developing severe clinical manifestations and acquisition episodes are milder. These studies also show that it is possible with vaccination to reduce the magnitude and duration of viral replication as well as the burden of latent infection within neurones.<sup>215</sup> The frequency of recurrences is also lower in vaccinated animals. The precise role of vaccines in future management of HSV disease is yet to be defined.<sup>213</sup> It is unlikely that vaccines will give complete protection, but partial protection is a realistic goal. Vaccines may also have a place in prevention of disseminated neonatal HSV infection. To date numerous vaccines have entered phase 2 and phase 3 programs but no commercially viable vaccine has been developed. Trials so far have shown that modification of the severity of acquisition illnesses, and a limited impact on the frequency and severity of recurrences is possible with some sub-unit glycoprotein vaccines<sup>54</sup> but a clinically useful effect in large-scale studies has not been demonstrated even when combined with potent immunogens.

Ultimately, a vaccine is the only practical measure to control disease and the spread of infection. The morbidity, mortality and economic impact of genital HSV are significant. Presently, prevention or amelioration of disease with or without partial protection against infection may be achievable with the vaccine,

**Table 28.10:** Types of HSV Vaccines

No. vaccine type	Status
1. Inactivated virion-derived vaccines (prepared from HSV infected cell cultures and contain both viral and cellular material).	Effective in experimental models but clinical trials have shown that they are not effective in humans.
2. Adjuvanted sub-unit vaccines (these vaccines consist of HSV proteins combined with adjuvants).	Recent trials of recombinant glycoprotein (gB2 +/- gD2) vaccines have shown limited success in phase II and failure in a large phase III study. <sup>54</sup> Failure of the 7000 patients Herpevac study of a subunit vaccine in women has recently been reported. <sup>218</sup>
3. Vectored vaccines (consist of an avirulent replication component viral or bacterial vector that has been engineered to express one or two HSV genes. Numerous vectors have been used to express HSV genes including vaccinia virus, adenovirus, varicella zoster virus and salmonella. Upon immunization the vector replicates producing the HSV gene products inducing immune response against HSV proteins).	Immunogenic and effective in animals.
4. Replication limited line viral vaccines (these vaccines are cycle without producing infectious progeny. Upon immunization, the vaccine virus infects cells and produces an aborted infection which induces immune responses).	Phase I clinical testing of one such vaccine (gH deleted) showed that vaccine is genetically engineered mutants that undergo a single replication—immunogenic. Phase II trials show only limited success to date <sup>219</sup>
5. Genetically attenuated live viral vaccines (these vaccines are replication competent HSV mutants that have had known virulence genes deleted so that they are incapable of causing disease).	Effective in animals. Human studies on going. Safety not confirmed.
6. Nucleic acid vaccines (these vaccines are based on the principle that injection of DNA encoding an immunogenic protein can induce the host to produce humoral and cellular immune responses directed against the encoded protein).	Effective in experimental models.

but it is difficult to know whether a partially protective vaccine will have a favorable impact on the ongoing epidemic of genital herpes. Thus, it is still not clear how a vaccine should be used and whether its use will be cost-effective.<sup>220</sup>

## Prevention

Two strategies can be adopted for prevention of HSV-2 transmission: (i) Interventions that will decrease viral shedding by infected persons, thereby decreasing the chance of exposure of uninfected individuals to the virus. (ii) Interventions that will render uninfected persons less susceptible to infection by the virus. Following measures can be helpful for prevention of HSV transmission:

- **Selective abstinence**<sup>221</sup>: Some patients may find this acceptable in high risk situations (e.g., third trimester of pregnancy). All patients should be advised to avoid sexual contact with unexposed partners during prodromes, lesional episodes, and in the first few days after a recurrence—this will require a degree of knowledge on the patient's part of the various manifestations of the condition as well as an appreciation of sub-clinical shedding and occasional atypical features.
- **Limiting number of sexual partners**: Levels of HSV2 in the population are correlated to sexual risk taking behavior. This may reduce the risk of acquiring genital herpes.
- **Avoiding partners who have a history of genital herpes**<sup>173,222</sup>: This does not help in prevention, as 80–90% of HSV-2 seropositive individuals have no signs or symptoms, yet they can transmit the virus to susceptible partners.
- **Consistent and correct condom use**: This may be the best practical approach to minimize the risk of acquiring genital herpes. Male latex condoms are effective at limiting acquisitions in both males and females. Consistent use is difficult to achieve but effects of protection in studies are visible even with inconsistent use. Condom usage on more than one in four occasions of sexual contact prevented 50% of HSV transmissions in a post hoc analysis of the various Chiron vaccine studies. Patients should be aware that condoms are not fully protective and that infectious virus can be shed from areas not protected or covered by barriers. There is no data for the effectiveness of the female condom.
- **Vaginal and rectal microbicides**<sup>223</sup>: This experimental approach is based on the theory that the virus can be inactivated at the portal of entry. One large study with tenofovir principally designed to look for an effect upon HIV transmission found a 50% reduction in HSV acquisitions.
- **Disclosure**: Sharing a genital HSV diagnosis with an unexposed partner is associated with a decreased risk of transmission per episode of sexual contact. The mechanism of this effect is presumably through better compliance with selective abstinence, and more consistent use of condoms. Many, possibly most patients, do not follow this advice to disclose their diagnosis—but for medicolegal purposes patients should be advised to consider this option.

- **Antiviral therapy**: This has been discussed above.
- **Vaccines**: As discussed above.

## Summary

Genital herpes is a disease of major public health importance. The last four decades have seen the emergence of HSV as the predominant cause of genital ulcer disease worldwide. The major morbidity of genital herpes is its propensity to recur frequently, its chronicity and its impact on the patient's psychosocial health. Many patients with genital herpes are unaware of their infection. When clinically apparent, clinicians need to be aware of the constellation of problems that can occur for patients and the need for careful counseling and support to manage the stigma and concern that most patients will suffer. Studies have shown the efficacy and safety of antiviral agents in controlling the symptoms of both acute and recurrent disease and in reducing serious complications particularly neonatal transmission. Concerns regarding onward transmission in relationships are common and judicious use of antiviral therapy along with patient counseling can minimize this risk. The epidemiological interactions and synergy between HSV-2 and HIV have drawn much interest in the last decade and the role of HSV-2 in fuelling the HIV epidemic has been clearly elucidated in recent studies.

# Anogenital Human Papillomavirus Infection: Natural History, Epidemiology, and Vaccination

David Rowen • Paul Fox • Peter Goon

# 29

## Introduction

The viral etiology for the development of human skin warts was proposed in the early 20th century, and viral particles were seen on electron microscopy of wart samples in the late 1960s.<sup>1,2</sup> In 1980, Gissman and zur Hausen, isolated and characterized Human Papillomavirus (HPV) type 6 from a genital wart, thus defining one of the two main HPV types responsible for the development of anogenital warts.<sup>3</sup> Subsequently, zur Hausen postulated the link between HPV and cervical cancer in 1976 and went on to identify HPV 16 and then 18 in cervical cancers in 1983–84. Progress in HPV research has been hampered by the inability to culture the virus *in vitro*, and the absence of satisfactory animal models. Major advances in molecular, biological techniques such as DNA amplification and splicing, have, in part, circumvented some of these difficulties. These advances, together with improved understanding of the epidemiology of papillomavirus infection in respect to cervical and other lower genital tract malignancy have proven to be a major impetus to HPV research.

## Viral Structure

HPV is an unenveloped DNA virus about 55 nm in diameter and consists of approximately 8000 base pairs. It exists in three forms: form I, in which the DNA strands are covalently closed, forming superhelical twists that characterize the infectious particle; form II, which is characteristic of the replicating virus, is an open circle of DNA whereas form III is linearized following single-cut restriction endonuclease treatment. More than a hundred types of papillomavirus have now been characterized, of which approximately 40 types are known to infect the lower genital tract (Table 29.1).<sup>4,5</sup> Typing is based upon DNA homology in the L1 sequence in which more than a 10% difference in sequence defines a new type.<sup>4–6</sup>

## Viral Subtypes and Natural History of Disease

The HPV types which infect the oral and anogenital regions belong to the subdivision of HPV termed the alpha-papillomaviruses.<sup>7</sup>

HPV 16 is responsible for the majority of cervical and anal neoplasms, with closely related types accounting for much of the remainder. A significant proportion of vulval cancers can be ascribed to HPV16 whereas the role of HPV in the pathogenesis of penile cancer is less well-defined. It can be difficult to determine whether a viral type found within a neoplasm is the causative agent or not. Within such a tissue there may be small areas infected with different viral types which will also be detected by PCR testing. The best quality data is that for cervical disease, but even here doubts remain as to whether some of the uncommon HPV types play any significant role in carcinogenesis. The technique

**Table 29.1:** Genital and Related Lesions Associated with Human Papillomavirus

Lesions	Predominant HPV types
Condyloma acuminata	6, 11.
Buschke–Löwenstein tumor	6, 11
Recurrent respiratory papillomatosis	6, 11
Carcinoma of head, neck, lung	16, 18, 30
Oral papilloma	6, 7, 11, 16, 32 (also 72, 73 in HIV patients)
Carcinoma of cervix	16 (55%), 18 (16%) global averages (WHO data) <sup>10</sup> Predominant minor types: 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66
CIN 1	Compared with cervical cancer prevalence of 16/18 is halved and prevalence of minor types is higher (WHO data)
CIN 2/3	16 (~ 42%), 18 (~ 7%), 31 (~ 7%), 58 (~ 8%) (WHO data).
Carcinoma of penis	16 (59% +) <sup>11</sup> Predominant minor types: 18, 35, 45.
Carcinoma of anus	16 (87%), 18 (7%), 33 (6%), 31 (1%) <sup>12</sup>
Other types occasionally associated with malignancy	40, 42–44, 53, 54, 59, 61, 68, 70, 72, 73, 81, 82 <sup>13</sup>

of laser capture micro-dissection allows extremely small areas of tissue to be sampled and analyzed, and should make it possible, in the future, to clarify some of unknowns with regard to the viral etiology of neoplasia, especially if combined with assays for HPV E6/E7 messenger RNA. A study by Insinga et al.<sup>9</sup> determined the rate of progression to cervical intraepithelial neoplasia (CIN) 1 following infection with HPV 16 and 18.<sup>8</sup> The annual progression rate was 8.3%. For CIN 2 and CIN 3, the annual incidence rate was 5.8% and 3.5%, respectively.

The encoded proteins may be divided into early (E1-7) and late (L1-2) gene products. The late gene products, L1 and L2, are structural capsid proteins, of which L1 protein makes up approximately 80% of the viral capsid, while the exact structural role of the minor capsid protein L2 has not been determined.

HPV can persist subclinically in basal epithelial cells by inducing a low rate of stable replication in infected cells through the E1 and E2 proteins. E1 is a helicase which binds to and interacts with host DNA, and E2 is involved in recruitment of E1 to the key target region. E2 also has a role in repressing transcription. In clinically evident lesions HPV has caused cells to enter into runaway or vegetative replication and the E6 and E7 proteins are crucial to this process. What factors determine whether replication is stable or becomes vegetative is unclear. E6 activates telomerase and thereby promotes continued cell proliferation, and inhibits apoptosis, while E7 inactivates the tumor suppressor gene pRb, allowing cells to enter the S phase, which is normally inhibited once cells have left the basal layer. In high-risk or oncogenic types of HPV the E6 protein has additional functions, notably the degradation of the apoptotic protein p53, and in conjunction with E7 blocks other growth arrest signals, resulting in immortalized cells. The degradation of pRb by E7 and of p53 by E6 is dependent on the human proteasome enzyme. The immortalized cells over a long period of time can thus acquire gene mutations which can give them the ability to penetrate the basement membrane and to grow within other tissues. Oncogenic HPV frequently becomes integrated into host DNA at widely variable locations, but this is not a pre-requisite for carcinogenesis.

## Immunopathology

Papillomaviruses are able to bind *in vitro* in a saturable fashion to a range of epithelial cell lines. Pre-treatment of cells with trypsin reduces the ability to bind virus, suggesting that the receptor for HPV is a cell-bound protein. Studies have demonstrated α6 integrin to be a receptor molecule for both HPV 6 and 16.<sup>14,15</sup> *In vivo*, the infective process follows microtrauma to the upper layers of genital skin or mucosa that facilitates entry of the virus to deeper layers where immature keratinocytes reside. It is infection of basal keratinocytes that may result in the development of warts and/or precursor lesions of squamous cell carcinomas. Spontaneous regression of warts has been reported. In a study by Coleman et al. regression was seen in 11% of patients.<sup>16</sup> This phenomenon was associated with increased numbers of CD4+

lymphocytes both within the wart stroma and at the surface epithelium. No increase in Langerhans cell numbers was found although there was induction of HLA-DR and ICAM-1 on keratinocytes in regressing warts. Given the immune events observed in spontaneously regressing warts and the observation that individuals with inherited immune deficiencies affecting T cell responses are more prone to HPV infection, it would appear that CMI responses are essential for the control of papillomavirus infection. The reasons why, even in immunocompetent subjects, there are poor CMI responses are not well-understood. However, antigen processing via professional antigen presenting cells, that is, dendritic cells and macrophages, does not appear to be efficient. This may in part be explained by the fact that the virus is not cytolytic nor does it not have a blood-borne stage. That humoral immunity has an important role to play is demonstrated by the efficacy of prophylactic vaccines (*vide infra*), but curiously, disorders of humoral immunity have not been associated with increased susceptibility to HPV-induced lesions.<sup>17</sup> A recent study demonstrated that wart-derived chemokines attracted FOXP3+ regulatory T cells in large genital warts leading to immune unresponsiveness.<sup>18</sup>

Immune evasion by HPV is achieved through several means. First, HPV is a non-cytolytic virus, and infectious particles are only produced in the upper epithelial layers at the end of the cell's lifespan and viral protein expression and replication is tightly bound to the maturation of the cell. The viral early proteins expressed in the lower epithelial layers are thought to be expressed at levels lower than those necessary for efficient triggering of the host immune response. Secondly, HPV can actively interfere with the host immune response through several of its early proteins, especially those of the high-risk HPVs. E5 interferes with HLA class II maturation and presentation,<sup>19</sup> E6 and E7 can interfere with E-cadherin expression and Langerhans cell density and can perturb function of Interferon Response Factor 3.<sup>20</sup> Therefore, there are multiple pathways by which HPV (especially HR-HPV) can evade the immune response.

## Histopathology

Histopathological features of condyloma acuminatum include slightly thickened stratum corneum, papillomatosis, and acanthosis of stratum malpighii, and thickening and elongation of the rete ridges (Fig. 29.1). There is a fibrovascular core. Other clinical variants (papular and macular) have the same features with less pronounced branching. The most characteristic feature for the diagnosis is the presence of epithelial cells with distinct perinuclear vacuolization. Such cells are known as "koilocytes" (Fig. 29.2). The vacuoles in koilocytes are sharply demarcated from the peripheral rim of condensed cytoplasm. The nucleus is hyperchromatic and large. It is important to remember that vacuolization is a normal feature in upper portion of mucosa, therefore, it is considered pathognomonic only if it extends to the deeper layers of stratum malpighii.

**Fig. 29.1:** Histology of genital wart—slightly thickened stratum corneum, papillomatosis and acanthosis of stratum malpighii, and thickening of rete ridges.

**Fig. 29.2:** Koilocytosis.

## Epidemiology

Anogenital warts are the most common manifestations of sexually transmissible HPV infection, and prevalence peaks during the second and third decades of life, in keeping with all other sexually acquired diseases. Reported prevalence rates of genital warts vary between 0.6% and 13% depending on the population studied.<sup>21</sup> Twenty year trends in the incidence and prevalence of diagnosed genital warts in Canada showed that the incidence reached (149.9/100,000 in men and 170.8/100,000 in women) in 1992 and has further increased in recent times.<sup>22</sup> Prevalence rates for HPV infection are, however, considerably greater. Conservative estimates suggest a two-fold increase in HPV 6 and 11 detection rates over that for the detection of warts, whereas Kataoka et al. reported a three-fold increase in detection rates of HPV using PCR technology compared with Dot blot and Southern blot analyses.<sup>23–25</sup> Genital warts as a manifestation of papillomavirus infection represent the tip of the iceberg (Fig 29.3) of HPV infection. Within the spectrum of subclinical infection there are several distinct entities, namely

**Fig. 29.3:** Manifestations of HPV infection.

acetowhite epithelium, macroscopically normal epithelium, but with cytological or histological evidence of HPV infection, such as koilocytosis, and finally macro- and microscopically normal epithelium in which HPV has been detected by such means as *in situ* hybridization or DNA amplification by PCR.

The infectivity of patients with warts is well-documented. Up to two-thirds of their sexual partners will, within six months, develop warts.<sup>26</sup> Given the high prevalence of sub-clinical infection, it is likely that transmission from sub-clinical lesions is common.<sup>17</sup> Occasionally, anogenital warts may be caused by papillomavirus types associated with hand warts, namely types 2 and 4.<sup>27</sup> Genital HPV is less common in circumcised men, and cervical cancer risk is reduced among female sex partners of circumcised men.<sup>28</sup>

Around 70% of genital HPV infections clear within 1 year and 90% within two years, leaving a small proportion of patients with more long-standing infection which might persist for decades. HPV 16 takes longer to be cleared by the immune system than other types, having a median duration of 8 months, compared to 3–4 months for HPV 6, 11, and 18. It has not been determined whether the virus can persist indefinitely undergoing stable replication without producing any further clinical warts or not, but in practical terms such questions are irrelevant for most patients.

## Laboratory Diagnosis

In majority of HPV-infected individuals, no visible lesions are apparent. In the absence of clinical manifestations, genital HPV infection can be difficult to detect. Diagnostic methods used to diagnose other viral infections (e.g., growing virus in cell culture) cannot be successfully applied to HPV. Therefore,

clinical diagnosis and cytologic alterations remain the most frequently applied diagnostic criteria for genital HPV.<sup>29</sup> Biopsy for histological confirmation may be required if there is concern about the development of intraepithelial neoplasia, for example, vulval intra-epithelial neoplasia, anal intra-epithelial neoplasia. Some authorities recommend biopsy if the lesion is of the macular or papular variety and the patient is over 35 years of age.<sup>30</sup> There is no evidence to support the use of HPV typing of anogenital warts; it does not add any information that is clinically useful. The role of cytology by Pap smear examination for features of koilocytosis and dyskaryosis and histology in the diagnosis of cervical neoplasia is well-established. Koilocytic cells are considered as part of the spectrum of the lowest grade of CIN 1. The sensitivity of Pap smear is poor, though specificity is very high (approximately 90%). To increase its sensitivity FDA has approved Hybrid capture HPV DNA test 2(HC2) to be performed in conjunction with Pap smear.<sup>31</sup> The HC2 test can detect as little as 1 pg of HPV DNA/ml; its sensitivity and specificity are almost comparable with PCR-based detection methods. The advantages of the HC2 test are the relatively simple handling and good reproducibility of results, which make this test the best standardized HPV detection method. While the exact HPV type cannot be identified “low-risk” (6, 11, 42, 43, 44) and “high-risk” (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68) HPV genotype groups (HR HPV and LR HPV) are detected.

Revised recommendations of American College of Obstetricians and Gynecologists (ACOG) for Pap smears.<sup>32</sup>

- Women from ages 21 to 30 be screened every two years instead of annually, using either the standard Pap or liquid-based cytology.
- Women aged 30 and older who have had three consecutive negative cervical cytology test results may be screened once every three years with either the Pap or liquid-based cytology.
